LINDSAY & BLAKISTON'S  
NEW MEDICAL PUBLICATIONS,  
AND  
NEW EDITIONS,

ISSUED DURING THE PRESENT SEASON.

*Trousseau's Clinical Medicine.* Volume IV.

FROM THE THIRD REVISED AND ENLARGED EDITION.

Lectures on Clinical Medicine, delivered at the Hotel Dieu, Paris, by A. TROUSSEAU, late Professor of Clinical Medicine, in the Faculty of Medicine, Paris, &c., &c. Vol. IV, Translated from the Third Revised and Enlarged Edition, by JOHN ROSE CORMACK, M.D., under the auspices of the NEW SYDENHAM SOCIETY of London, and published in the United States by arrangement with them. Octavo, Cloth. Price, . . \$4.00

CONTENTS OF VOLUME IV.

LECTURE 68, Dyspepsia; 69, Chronic Gastritis; 70, Simple Chronic Ulcer of the Stomach; 71, Diarrhœa, Chronic Diarrhœa; 72, Infantile Cholera, Diarrhœa of Children; 73, Lactation, First Dentition, and the Weaning of Infants; 74, Dysentery; 75, Constipation; 76, Fissure of the Anus; 77, Intestinal Occlusions; 78, Hepatic Colic, Biliary Calculus; 79, Hydatid Cysts of the Liver; 80, Malignant Jaundice; 81, Syphilis in Infants; 82, Gout; 83, Nodular Rheumatism, erroneously called Rheumatic Gout; 84, Acute Articular Rheumatism, and Ulcerating Endocarditis.

RECENTLY PUBLISHED.

Volumes I, II, and III of the same work, handsomely bound in cloth to match.  
Price, \$5.00 each.

Trousseau's Lectures on Clinical Medicine, so favorably received, as well by the profession of the United States as abroad, are published in this country in connection with the New Sydenham Society, under whose auspices the translation of Vols. II, III and IV have been made. Either volume can be furnished separately, and in order to still further extend the circulation of so valuable a work, the Publishers have reduced the price of the first three volumes to *Five Dollars* per volume, and will furnish Vol. IV at *Four Dollars*.

"Trousseau furnishes us with an example of the best kind of Clinical Teaching. It is a book that deserves to be popularized. The translation is perfect."—*Medical Times and Gazette*.

"The great reputation of Prof. Trousseau as a practitioner and teacher of Medicine in all its branches, renders the present appearance of his Clinical Lectures particularly welcome."—*Medical Press and Circular*.

"The publication of Trousseau's Lectures will furnish us with one of the very best practical treatises on disease as seen at the bedside."—*British and Foreign Medico-Chirurgical Review*.

"A clever translation of Prof. Trousseau's admirable and exhaustive work, the best book of reference upon the Practice of Medicine."—*Indian Medical Gazette*.

"The Lectures of Trousseau, in attractiveness of manner and richness of thoroughly practical matter, worthily takes a place beside the classical lectures of Watson and Graves."—*British Medical Journal*.

"Trousseau is essentially the French Graves, and his lectures should sooner than this have been translated into English."—*Lancet*.

*Growths in the Larynx*, THEIR HISTORY, CAUSES, SYMPTOMS, DIAGNOSIS, PATHOLOGY, PROGNOSIS, AND TREATMENT, with Reports and an Analysis of one hundred Consecutive Cases treated by the author, and a Tabular Statement of every published case treated since the invention of the Laryngoscope. By MORELL MACKENZIE, M.D., Physician to the Hospital for Diseases of the Throat, author of "The Laryngoscope," "Diseases of the Throat," &c. Profusely illustrated by 87 elegantly executed Wood Engravings, together with a number of Lithographic figures, and Chromo-Lithograph, or Colored, Illustrations, forming a handsome Octavo volume, printed on Cream Tinted Paper. Price, \$3.00

"This book is undoubtedly the most complete and original essay on new formations in the Larynx which has appeared in this country. The author's comparisons of the merits of the operations, and the rules he lays down for the guidance of the practitioner, are by no means the least valuable portion of a book, which we can cordially recommend to our readers."—*Medical Times and Gazette*.

"The Use of the Laryngoscope in Diseases of the Throat, and Essays on Growths in the Larynx, are two monographs of first-rate merit. Dr. Mackenzie's Essays would do honor to any place; and he has used the opportunities afforded to diligence and skill to make solid and enduring contributions to science and practice. Both works are, throughout, models of honest and complete work, and are honorable to British medicine, as they are useful to practitioners of every country. The completeness of the clinical records, the abundant graphic illustrations, and the fulness of bibliographical references, are excellent features in both volumes."—*British Medical Journal*.

BY SAME AUTHOR, SECOND EDITION.

*The Use of the Laryngoscope in Diseases of the Throat*. With an appendix on Rhinoscopy, and an Essay on Hoarseness, and Loss of Voice, with additions, by J. SOLIS COHEN, M.D., Author of "Inhalation, Its Therapeutics and Practice," &c. Illustrated by two Lithographic Plates, and 51 Engravings on Wood. Price, . . \$3.00

*Acton's Functions and Disorders of the Reproductive Organs in Childhood, Youth, and Advanced Life*.

By WILLIAM ACTON, M.D. Third American from the Fifth London Edition. Octavo. Price, . . . . . \$3.00

"Mr. Acton has devoted himself for many years with unwearying assiduity to the study of the diseases of the reproductive organs, after an intimate acquaintance with syphilitic diseases gained in the Clinique of M. Ricord; and we accordingly find that whether as regards the structure, the functions, or the diseases of the organs in question, every circumstance has received the minutest attention. . . . ."—*Medical Times and Gazette*.

"In the work now before us, all essential detail upon its subject-matter is clearly and scientifically given. We recommend it accordingly, as meeting a necessary requisition of the day."—*The Lancet*.

"We think Mr. Acton has done good service to society by grappling manfully with sexual vice, and we trust that others whose position as men of science and teachers enable them to speak with authority will assist in combating and arresting the evil which it entails. We are of the opinion that the spirit which pervades it is one that does credit equally to the head and to the heart of the author."—*The British and Foreign Medico-Chirurgical Review*.

*Gant's Science and Practice of Surgery*.

A Complete Text-Book including the Principles and Practice, by FREDERICK J. GANT, F.R.C.S., Surgeon to the Royal Free Hospital, London, &c., &c. With 471 Illustrations, and over 1100 Octavo pages. Price, . . \$7.50

Dr. Gant's Surgery is similar in its general features to Dr. Errickson's excellent Text-Book on the Science and Practice, as comprising the *whole* of surgery, but it will have the great advantage of being an entirely new work, and appearing in a greatly condensed form, without the omission of any important subject. The matter throughout is fully brought up to the present time,—many original sources of information, including the best treatises in Holmes's System of Surgery, having been utilized, which have not heretofore been gathered into any general work on surgery, thus making it a more complete book for the student, and a work of ready reference for the practitioner. It is also illustrated by 471 new illustrations, which add much to its value.

## *Pereira's Physicians' Prescription Book.*

THE FIFTEENTH EDITION.

Containing Lists of Terms, Phrases, Contractions, and Abbreviations, used in Prescriptions, with Explanatory Notes, the Grammatical Constructions of Prescriptions, Rules for the Pronunciation of Pharmaceutical Terms, A Prosodiacal Vocabulary of the Names of Drugs, &c.; and a series of Abbreviated Prescriptions illustrating the use of the preceding terms, &c.; to which is added a Key, containing the Prescriptions in an unabbreviated form, with a Literal Translation, intended for the use of Medical and Pharmaceutical Students. By JONATHAN PEREIRA, M.D., F.R.S., &c.

Price, in Cloth, \$1.25; in Tucks, with pocket, \$1.50

"Although intended chiefly for the Medical practitioner and student, it will be found exceedingly convenient and useful for the Apothecary. There are many points of usefulness and interest in the book which claims for it a place in the Library of every pharmaceutical student."—*American Journal of Pharmacy.*

## *Wythes's Physician's Pocket Dose and Symptom Book.* THE TENTH EDITION, REVISED.

Containing the Doses and Uses of all the Principal Articles of the Materia Medica, and Original Preparations; A Table of Weights and Measures, Rules to Proportion the Doses of Medicines, Common Abbreviations used in writing Prescriptions, Table of Poisons and Antidotes, Classification of the Materia Medica, Dietetic Preparations, Table of Symptomatology, Outlines of General Pathology and Therapeutics, &c. By JOSEPH H. WYTHES, A.M., M.D., &c.

Price, in cloth, \$1.25; in tucks, \$1.50

This little manual has been received with much favor, and a large number of copies sold. It was compiled for the assistance of students, and to furnish a vade-mecum for the general practitioner, which would save the trouble of reference to larger and more elaborate works. The present edition has undergone a careful revision. The therapeutical arrangement of the Materia Medica has been added to it, together with such other improvements as it was thought might prove of value to the work.

## *Pulmonary Consumption; Its Nature, Varieties, and Treatment.*

With an Analysis of One Thousand Cases to exemplify its duration. By C. J. B. WILLIAMS, M.D., F.R.S., Senior Consulting Physician to the Hospital for Consumption, and CHARLES THEODORE WILLIAMS, M.D., Physician to the Hospital for Consumption, &c. Price, . . . \$3.50

## *Prince's Plastic and Orthopedic Surgery.* Containing

PART I. A Report on the Condition of, and Advances made in, Plastic and Orthopedic Surgery, up to the Year 1871. PART II. A New Classification and Brief Exposition of Plastic Surgery. With numerous illustrations. PART III. ORTHOPEDICS: A Systematic Work upon the Prevention and Cure of Deformities. With numerous Illustrations. Octavo. Price, \$4.50

## *Lindsay & Blakiston's Physician's Visiting List* for 1872. SIZES AND PRICE.

*Rihl & O'Conner's Physician's Diary*, Monthly, Semi-Annual, and Annual Journal and Cash-Book Combined. The Fourth Revised Edition. A large folio volume, with Printed Heads, Index, &c., &c. Bound in full leather. Price, . . . . . \$7.50

## *Harris's Principles and Practice of Dentistry.*

### THE TENTH REVISED EDITION.

In great part rewritten, rearranged, and with many new Illustrations. Revised and edited by P. H. AUSTEN, M.D., Professor of Dental Science and Mechanism in the Baltimore College of Dental Surgery, assisted by Prof. GORGAS and THOS. S. LATIMER, M.D. With 400 Illustrations.

Price, in Cloth, \$6.50; in Leather, 7.50

## *Meadows's Manual of Midwifery.* A NEW TEXT-BOOK.

Including the Signs and Symptoms of Pregnancy, Obstetric Operations, Diseases of the Puerperal State, &c., &c. By ALFRED MEADOWS, M.D., Member of the Royal College of Physicians, &c., &c. First American from the Second London Edition, with numerous Illustrations. Price, . . \$3.00

*Dillnberger's Handy-Book of the Treatment of Women and Children's Diseases*, according to the Vienna Medical School. Translated from the Second German Edition, by P. NICOL, M.D. Price, . . . . . \$1.75

## *Byford on the Uterus.* SECOND EDITION.

On the Chronic Inflammation and Displacements of the Unimpregnated Uterus. By W. A. BYFORD, A.M., M.D., Professor of Obstetrics, and Diseases of Women, in Chicago Medical College; and author of "The Practice of Medicine and Surgery, Applied to the Diseases of Women." A New, Enlarged, and thoroughly Revised Edition, with numerous Illustrations. One volume, Octavo. Price . . . . . \$2.00

## *Tanner and Meadows's Practical Treatise on the Diseases of Infancy and Childhood.*

By THOMAS HAWKES TANNER, M.D. The Third American from the last London Edition, by ALFRED MEADOWS, M.D., author of "A Manual of Midwifery," &c., &c. One volume. Price, . . . . . \$3.50

## *Tilt's Change of Life in Health and Disease.*

A Practical Treatise on the Nervous and other Affections incidental to Women at the Decline of Life. By EDWARD JOHN TILT, M.D. From the Third London Edition. In one volume Octavo. Price, . . \$3.00

## *Duchenne's Localized Electrization.*

Translated from the Third Edition, by HERBERT TIBBITTS, M.D., L.R.C.P. Lond., Medical Superintendent of the National Hospital for the Paralyzed and Epileptic. With 92 Illustrations, and Notes and Additions by the Translator. Price, . . . . . \$3.00

## *Wright on Headaches.* A NEW EDITION.

Their Causes and Their Cure. By HENRY G. WRIGHT, M.D., Member of the Royal College of Physicians, &c., &c. From the Fourth London Edition. Price, . . . . . \$1.25

## *Reynolds's Lectures on the Clinical Uses of Electricity.*

delivered at the University College Hospital, by J. RUSSELL REYNOLDS, M.D., F.R.S., Professor of the Principles and Practice of Medicine, University College, London, editor of "A System of Medicine," &c., &c. One volume, Post Octavo. Price, . . . . . \$1.50

## *Paget's Surgical Pathology.* THIRD LONDON EDITION.

Lectures delivered at the Royal College of Surgeons of England, by JAMES PAGET, F.R.S., Surgeon to Bartholomew and Christ's Hospital, &c., &c. The Third London Edition, Edited and Revised by WILLIAM TURNER, M.B., Lond., Senior Demonstrator of Anatomy in the University of Edinburgh, &c., &c. In one volume, Royal Octavo. With numerous Illustrations. Price, . . . . . \$7.50

"It would be very superfluous for us to say many words in calling the attention of the profession to this new edition of Mr. Paget's great work on Surgical Pathology. Its author has been singularly fortunate in securing the assistance (for this edition) of so able a collaborator as Mr. Turner, and English surgery may point with pride to the present volume as one unsurpassed, if it is at all equalled in the surgical literature of the world, in breadth of view and philosophical grasp of its subject."—*Practitioner*.

## *Beasley's Druggists' Receipt Book.* SEVENTH AM. ED.

Comprising a copious Veterinary Formulary, numerous Receipts of Patent and Proprietary Medicines, Druggists' Nostrums, &c.; Perfumery and Cosmetics, Beverages, Dietetic Articles and Condiments, Trade Chemicals, Scientific Processes, and an Appendix of Useful Tables, by HENRY BEASLEY, author of the Book of Prescriptions, &c., &c. Price, . . . \$3.50

# Rindfleisch's Text-Book of Pathological Histology. 208 Illustrations.

*An Introduction to the Study of Pathological Anatomy.* By Dr. EDWARD RINDFLEISCH, O. O. Professor of Pathological Anatomy in Bonn. Translated from the Second German Edition, by WM. C. KLOMAN, M. D., assisted by F. T. MILES, M. D., Professor of Anatomy, University of Maryland, &c., &c.

## CONTENTS.

Introduction, Author's and Editor's Prefaces.

### GENERAL PART.

1. Decomposition and Degeneration of Tissues.
2. Pathological New Formations.

### Index and Bibliography.

Containing 208 Elaborately Executed Microscopical Illustrations.

One volume, octavo. Price, cloth, \$6.00; sheep, \$7.00.

Prof. Rindfleisch's Text-Book of Pathological Histology, so justly celebrated in Germany, where it is considered the most complete and thorough work of its kind, having passed rapidly to a second edition, is also very highly valued and commended by German Medical scholars in this country, many of whom are not only familiar with the book, but with the author's great reputation as a teacher and professor of this branch of medical study.

The translators are both gentlemen who by their past education have been peculiarly fitted for the task of translating the work. Dr. Kroman from early life has been familiar with the German language, while Prof. Miles has made the subject one of special study, both gentlemen being also practical microscopists. The Publishers therefore offer a translation of this truly valuable work to the Medical Profession in the United States, feeling the utmost confidence that in both manner and style it will prove acceptable to them. In their Preface, the Translators say: "In presenting the English reading portion of the Medical Profession with a translation of the valuable work of Prof. Rindfleisch, the translators scarcely deem an apology necessary. The merits of the book itself, and the fact that it fills an unoccupied gap in our most recent literature upon the subject of Pathological Histology, was judged to be an ample incentive for undertaking the labor of the translation. The work of VIRCHOW translated by CHANCE, is, in many points, antiquated, and the more recent work of BILBROTH, translated by HACKLEY, occupies the ground but partially, and is professedly a work of Surgical Pathology."

This book is translated and published in this country by special arrangement with the author.

# *Waring's Practical Therapeutics.* A NEW EDITION.

Considered chiefly with reference to Articles of the *Materia Medica*.

By EDWARD JOHN WARING, F.R.C.S., F.L.S., &c., &c. Second American, from the Third London Edition. Royal Octavo.

Price in Cloth, \$5.00; Leather, 6.00.

There are many features in Dr Waring's *Therapeutics* which render it especially valuable to the Practitioner and Student of Medicine, much important and reliable information being found in it not contained in similar works; it also differs from them in its completeness, the convenience of its arrangement, and the greater prominence given to the medicinal application of the various articles of the *Materia Medica* in the treatment of morbid conditions of the Human Body, &c. It is divided into two parts, the alphabetical arrangement being adopted throughout; there is also added an excellent INDEX OF DISEASES, with a list of the medicines applicable as remedies, and a full INDEX of the medicines and preparations noticed in the work.

"This new edition of *Waring's Practical Therapeutics* has been altered and improved with great judgment. A satisfactory account of new agents—chloral, apomorphia, nitrous oxide, carbolic acid, &c., is introduced without adding to its bulk. The additions are made with remarkable skill in condensation. It is one of the best manuals of therapeutics yet in existence."—*Brit. Med. Journal*.

"There has been no scarcity, latterly, of works of this class, several of them we regard as having great professional value; but, it must be allowed, we think, that this holds no inferior place among them. Still it is a national book, but much more voluminous; and, therefore, while it is high authority, it is less convenient for office use. Furthermore, we prefer the literary arrangement and execution of *Waring*. It can be used with more readiness and always relied on for the correctness of its facts. In the daily treatment of diseases, it seems to supply everything that can be desired. The articles are arranged alphabetically, and a paragraph is devoted to their physical description and scientific character. Their therapeutic uses, however, constitute the bulk of the volume; and in this respect the labor has been very thorough."—*Druggists' Circular*.

"The plan of this work is admirable, and well calculated to meet the wants of the busy practitioner. There is a remarkable amount of information, accompanied with judicious comments, imparted in a concise yet agreeable style. The indications for the application of remedies are sufficiently comprehensive, and their mode of action generally accounted for on rational grounds. The publishers have well performed their part, and we trust that their enterprise in introducing the work to the profession in America may meet with that encouragement which the inherent merits of the treatise itself are entitled to command."—*Medical Record*.

"Our admiration, not only for the immense industry of the author, but also of the great practical value of the volume, increases with every reading or consultation of it. We wish a copy could be put in the hands of every student or practitioner in the country. In our estimation it is the best book of the kind ever written."—*N. Y. Medical Journal*.

"It is, indeed, one of the most practical works that has ever attracted our attention. Combining the merits of Wood, Beck, Still, and the U. S. Dispensatory, it forms a volume which no young physician can afford to be without."—*Chicago Medical Journal*.

"This work is a monument of industry and perseverance, invaluable both to the Practitioner and Student."—*Canada Medical Journal*.

"Mr. Waring has produced a volume which entitles him to the thanks of Students as well as of all who need a work on Therapeutics."—*American Medical Journal*.

"A more laborious, painstaking, and valuable composition does not exist in any other language on the subject: one that should be in every practicing Physician and Surgeon's study, without which their libraries, no matter how rich otherwise in works on *Materia Medica*, must of necessity be incomplete."—*Dublin Quarterly Journal of Medicine*.

"No work on this subject has appeared that can be more fully recommended to the Student and Physician. It not only contains all that is actually necessary to the Practitioner, but affords otherwise, much useful, valuable, and novel instruction. The oldest Physician and the most accurate Student will find in it much that has not, and cannot be seen elsewhere. No one can consult its pages without receiving practical information and judicious counsel."—*Richmond Medical Journal*.

## PREFACE.

---

It is now many years since a new systematic work representing the Science and Practice of Surgery, has appeared in this country.

In offering this to the Profession, as the most recent one, I have endeavoured to introduce a full but condensed embodiment of all those changes in the Pathology and Treatment of Injuries and Diseases, which the progress of Surgery has *established*.

The leading features of this work are these:—It is essentially *descriptive*—not theoretical. In describing the various forms of Injury and Disease, I have endeavoured to present a sound and enlarged view of Surgical Pathology; but exhibiting, more particularly, the *guiding elements* of their pathology—whether for the purpose of study or reference. The whole is *uniformly arranged* under three heads—(1) Structural condition, with its Signs or Symptoms, and Diagnosis; (2) Causes, and Effects of the morbid condition; (3) Course, Terminations, Consequences, and Prognosis. The primary importance of all that pertains to the Diagnosis, or detection and discrimination of morbid conditions, has induced me to introduce a brief description of the healthy Anatomy of the part; wherever this seemed necessary or convenient, to clearly understand the nature of the structural alterations in Disease or Injury; or for guidance in Surgical Operations. Thus will be found the Surgical Anatomy of the region or parts concerned, in relation to Herniæ; and, of the Arteries, in connexion with Ligature. Physiology is interwoven with the Pathology of morbid conditions. (4) Treatment is fully considered—the *pathological indications* being stated, with guiding rules of treatment; and their fulfilment, both by medicinal agents—so far as the remedial efficacy of medical treatment may be at present known—and by the appropriate Surgical *Operations* or manipulations,—the design and performance of which are carefully described in detail. The various kinds of Surgical Instruments and *Apparatus* are also specially noticed, and their mode of application explained.

Statistical Results of Treatment, are appended whenever usefully illustrative of the curative value of Surgical Operations.

The range of this work, in respect to its subject-matter, will be seen on perusing the Table of Contents. The Introduction presents a pre-

liminary view of the nature of Surgery, as a Science and an Art ; the latter, principally in regard to Operations, the Conditions favourable or unfavourable for their performance ; the Arrangements necessary as to Instruments and Assistants ; Anæsthetics, especially Chloroform ; the Dangers attending or consequent on Operations, and their Results. Then follows the recognised division of Pathology and Surgery into Two Parts—General, and Special ; and the latter is arranged under Two Divisions—Injuries and Diseases of Textures, and those of Organs and Regions.

Part I.—General Pathology and Surgery, comprising the forms of Disease which are common to all parts of the body, is made more comprehensive than in other systematic works ; it being the source of guidance in all Surgical Practice. This Part relates to Inflammation, Tumours or Morbid Growths, Degenerations, Ulceration and Mortification. Then follow also Diseases of the Blood—as Scrofula, Scurvy and Purpura, Rheumatism and Gout ; Diseases of Contagious Origin—as Syphilis, Erysipelas, Pyæmia, Hospital Gangrene, Poisoned Wounds, Hydrophobia, Malignant Pustule, Glanders ; Diseases of the Nervous System—Shock of Injury, Prostration with Excitement, Tetanus. In Part II.—Special Pathology and Surgery, relating to the Textures, comprises the Injuries and Diseases of the Skin, and subjacent textures, in succession ;—as Wounds, Burns, Cellulitis ; Aneurisms, and Diseases of Arteries ; Fractures, and Diseases of Bone ; Dislocations, and Diseases of Joints ; Deformities ; Excisional Surgery of the Joints and Bones ; Amputations. As relating to Organs and Regions, this Division, beginning with the Head, and proceeding downwards in the body, is made equally comprehensive, so as to include a condensed view of each Special Branch of Surgery. Thus, it embraces, Diseases of the Eye, Ear, and Teeth, which belong respectively to Ophthalmic, Aural, and Dental Departments of Surgical Practice.

The Regional association of morbid conditions is especially calculated to facilitate the study of Diagnosis ; and the arrangement of pathological and surgical knowledge—relative to each form of Injury and Disease, throughout the work, will be found most serviceable as a preparation for the order of Clinical investigation, and record of cases. By constantly having regard to the selection of essential matter, and pursuing the uniform arrangement laid down ; I have thus, also, I trust, simplified, and not inconsiderably abridged the size of this work, as compared with those of similar character. These features will perhaps make it better adapted for the use of Students, as a Surgical Text-book ; while, the wide range of subjects, may render it more completely serviceable to the Practitioner, for reference.

The “ Science and Practice ” is quite independent of the Author’s “ Principles of Surgery,” although the two works have this relation : the one forms a systematic *description* of injuries and diseases, taken in-

*dividually*, in their pathology and treatment; the other is a systematic *exposition* of the guiding doctrines of all diagnosis, etiology, prognosis and therapeutics, from an original analysis of *general* pathology in the different classes of injury and disease. References to the Principles, for the convenience of those readers who have that work, are indicated, in the course of this work, by P. with the page, in brackets; as thus, [P. p. .]

As a general representation of Surgery, many sources of information have necessarily contributed; and it would be almost impossible to name individually, all those to whom by their published writings, I am indebted. The majority are acknowledged in foot-notes, or in the text. Some, whose labours have long since been established in surgical literature, are omitted. Of more recent sources of original information, not hitherto gathered into a work of this kind, I may here more particularly mention my indebtedness to many of the elaborate treatises in "the System of Surgery," by various authors, edited by Mr. T. Holmes. Thus, taking them in alphabetical order, I am under obligation to—Mr. Birkett, on Hernia and on Diseases of the Breast; Dr. Brown-Séquard, on Diseases of the Nerves; Mr. Holmes Coote, on Diseases of the Thyroid Gland; Mr. J. Dixon, on Diseases and Injuries of the Eye; Dr. George Harley, on Apnœa; Mr. E. Hart, on Aneurism; Mr. Charles Hawkins, on Lithotrity; Mr. Prescott Hewett, on Injuries of the Head; Mr. Hinton, on Diseases of the Ear; Mr. T. Holmes, on Aneurism, and on Diseases of the Bones; Mr. T. K. Hornidge, on General Pathology of Fractures; Dr. G. M. Humphry, on Diseases of the Male Organs of Generation; Mr. Jonathan Hutchinson, on Surgical Diseases of Women; Mr. Athol Johnson, on Diseases of the Joints; Mr. H. Lee, on Syphilis; Dr. W. J. Little, on Orthopædic Surgery; Mr. T. Longmore, on Gunshot Wounds; Mr. C. H. Moore, on Cancer; Sir James Paget, on Tumours; Mr. A. Poland, on Urinary Calculi and Lithotomy; Mr. G. D. Pollock, on Diseases of the Mouth and Alimentary Canal; Mr. S. James A. Salter, on Surgical Diseases connected with the Teeth; Mr. W. S. Savory, on Hysteria; Mr. A. Shaw, on Disease of the Spine; Mr. J. Simon, on Inflammation; Mr. Henry Smith, on Diseases of the Rectum; Sir H. Thompson, on the Surgery of the Male Urinary Organs.

I have also had recourse to other standard Treatises, recently published; and notably to—Hamilton, on Fractures and Dislocations; W. Adams, on Subcutaneous Surgery; Mr. R. Barwell, on Lateral Curvature of the Spine; Lockhart Clarke, on Tetanus; John Wood, on Rupture; Mr. Christopher Heath, on Diseases of the Jaws; Mr. Butcher's Operative and Conservative Surgery; Sir William Fergusson's Practical Surgery; Curling, on Diseases of the Testis, and on Diseases of the Rectum.

Many valuable Papers also in the Transactions of the Royal Medico-Chirurgical, and other Societies, have been levied; and Original Com-

munications to the Medical Quarterlies and Weekly Journals. Nor have I hesitated to avail myself of the latest Editions of other Systematic Works on Surgery, already familiar to the Profession—the works of Erichsen, Pirrie, and Druitt; gleaning wherever I could find anything new and important, or specially considered. Lastly, I have to thank several of my Professional brethren for having favoured me with notes on points of experience; and Mr. Hancock, for having kindly placed at my disposal the unpublished MSS. of his valuable Lectures on the Surgery of the Foot and Hip,—as delivered at the Royal College of Surgeons.

My own Pathological observations and Surgical experiences are interspersed throughout the work. Thus, I may be permitted to allude to Reparation in Wounds, Fractures, and after Injury of Arteries and Veins; Acupressure, Ligature, and Torsion of Arteries; the Pathological Conditions of Contused and Lacerated Wounds, of Compound Fractures, and of Compound Dislocations, which severally require Amputation; Dislocation of the Elbow-joint; Tumours; Degenerations; Polypus nasi; the Irritable Bladder; and, Diseases of the Joints, chiefly with reference to Excision,—being the Author's Lettsonian Lectures, on “Excisional Surgery,” as delivered before the Medical Society of London, 1871.

A carefully compiled Index, in conclusion, will be found convenient for reference.

After all my labour I am fully conscious of many shortcomings in my endeavour to do justice to the present state of Surgery; but I must plead the unaided, single-handed production of the work, on a subject so comprehensive, and pursued for years amid the daily interruptions of Professional avocations, public and private.

Of the Wood Engravings, 470 in number, which illustrate, and I trust adorn, the following pages, many are original,—the drawings having been taken from cases which have come under my own observation. Those which relate to Excisional Surgery were drawn by Mr. C. D'Alton, with his well-known accuracy. But, with regard to the larger proportion of the engravings, I am under obligation to my Publishers, Messrs. J. and A. Churchill, who have aided me in the most liberal spirit, with regard to the whole of their large collections of unsurpassed Wood-blocks, which originally illustrated Sir Astley Cooper's “Fractures and Dislocations,” edited by B. Cooper; those in Liston's “Practical Surgery;” and more recently in Fergusson's “Practical Surgery.” Sir William Fergusson himself most readily concurred in this arrangement—an additional kindness to many others—and thus enabled me to enrich this work with a large assortment of instruments and apparatus peculiar to Modern Surgery; and also to illustrate the Operations which he has either devised or modified, and with which the association of his

name is familiar; especially Lithotomy and Lithotrity, Operations for Tumours of the Jaws, and that for Cleft-Palate. My friends, Mr. John Wood, and Mr. William Adams, have equally obliged me in regard to the illustrations of their operations, for the Radical Cure of Hernia, and Subcutaneous Section of the Neck of the Femur. I have, moreover, to thank Mr. Heather Bigg, for having permitted me to select, aided by his own judgment and experience, any number of the wood-blocks I thought fit to use from his well-known Manual on "Orthopraxy." They are chiefly to be found in the Chapter on Deformities.

Under cover, I have taken this opportunity of publishing that which will be useful to all those who may be preparing for Examination at the Royal College of Surgeons of England, and which cannot fail to be interesting to the Profession at large,—a Guide to the Examinations for the Diplomas of Member and Fellow. It was written from personal observation during the last two years (1870-1); and, it exhibits the whole course of Examination in detail;—the nature of the Anatomical and Pathological Preparations, Surgical Instruments and Apparatus, and of the Questions, &c., submitted to Candidates,—in both the "Written" and "Practical," and of the "Primary," and "Pass," Examinations; with also the "Regulations" of the College relating thereto.

F. J. GANT.

*September, 1871.*

# CONTENTS.

## INTRODUCTION.

SURGERY, as a primary division of MEDICINE; as a Science and a Scientific Art. The relative importance of Diagnosis, Etiology, and Prognosis; and their relation, severally, to Treatment. The relative guidance of PATHOLOGICAL ANATOMY and of PATHOLOGY. Also, in the design and performance of Surgical Operations. Comparison of the Continental and English Schools of Surgery.

CONDITIONS Favourable and Unfavourable for Operation. Preparation of Patient. Arrangements for Operation—The Room, Table, Instruments, Assistants. Anæsthetics. Historical notice. Chloroform—its Physiological Action. Phenomena or Symptoms. Contra-indications to the employment of Chloroform, and exceptional Operations. Administration of Chloroform, and signs of anæsthesia. Inhalers. Death from Chloroform—by Asphyxia, Cardiac Syncope, Coma, persistent sickness. Treatment of an overdose. Other Anæsthetics—Nitrous Oxide or Laughing Gas. Sulphuric Ether. Bichloride of Methylene. Chloral. Local Anæsthesia. Freezing—by frigorific mixtures, ether-spray. Dangers attending, or consequent on, Surgical Operations. Dressing of the Wound, and Constitutional After-treatment. Results of Operation—Temporary, Permanent. Modes of Unsuccessful Results.

## PART I.

### GENERAL PATHOLOGY AND SURGERY.

#### DISEASES OF NUTRITION.

##### CHAPTER I.—INFLAMMATION.

	PAGE
NUTRITION . . . . .	20
Inflammation . . . . .	23
Textural Changes, and State of the Circulation and Blood-vessels . . . . .	23

## PART II.

## SPECIAL PATHOLOGY AND SURGERY.

## DIVISION I.

## INJURIES AND DISEASES OF TEXTURES.

## SKIN AND SUBJACENT TEXTURES.

CHAPTER XIV.—WOUNDS—INCISED WOUND, WOUNDS OF  
ARTERIES AND VEINS.

Incised Wound . . . . .	243
Reparation . . . . .	244
Immediate Union . . . . .	245
Primary Adhesion . . . . .	245
Suppurative Granulation and Cicatrization . . . . .	246
Healing under a Scab . . . . .	246
Modelling Process . . . . .	247
Treatment . . . . .	248
Antiseptic Dressings . . . . .	251
Theory of Antisepticism . . . . .	253
Results . . . . .	254
Wounds of Arteries . . . . .	255
Reparation . . . . .	256
Treatment . . . . .	258
Compression . . . . .	259
Ligature . . . . .	259
Acupressure . . . . .	261
Torsion . . . . .	264

WOUNDS—*continued*.

Wounds of Veins . . . . .	266
Entrance of Air into Veins . . . . .	267

CHAPTER XV.—CONTUSION—CONTUSED AND LACERATED WOUNDS—  
PUNCTURED WOUNDS.

Contusion . . . . .	268
Treatment . . . . .	270
Contused and Lacerated Wounds . . . . .	270
Treatment . . . . .	274
Amputation . . . . .	275
Punctured Wounds . . . . .	276
Treatment . . . . .	278

## CHAPTER XVI.—GUNSHOT WOUNDS.

Structural Conditions . . . . .	278
Projectiles . . . . .	282
Consequences . . . . .	284
Prognosis . . . . .	285
Treatment . . . . .	285
Amputation . . . . .	288
Excision . . . . .	289

## CHAPTER XVII.—MORBID CICATRICES.

Deficient Cicatrix. . . . .	289
Excessive, and Exuberant—Cheloid Cicatrix . . . . .	290
Painful Cicatrix . . . . .	291
Ulceration—Growths and Degenerations of Cicatrix . . . . .	291

## CHAPTER XVIII.—BURNS AND SCALDS. LIGHTNING. FROST-BITE.

Burns and Scalds . . . . .	292
Course and Terminations. . . . .	294
Treatment . . . . .	297
Lightning . . . . .	299
Frost-bite . . . . .	300

## CHAPTER XIX.—CELLULITIS. CARBUNCLE, AND BOILS.

Cellulitis . . . . .	301
Symptoms and Diagnosis. . . . .	301
Treatment . . . . .	302
Carbuncle or Anthrax . . . . .	302
Treatment . . . . .	303
Boil or Furunculus . . . . .	304
Chilblain . . . . .	305
Whitlow or Paronychia . . . . .	305
Onychia . . . . .	307
In-grown Toe-nail . . . . .	307
Corns. Horns. Warts . . . . .	308

## MUSCLES AND TENDONS.

CHAPTER XX.—SPRAIN. RUPTURE. TUMOURS.	PAGE
Sprains or Strains . . . . .	309
Rupture of Muscle and Tendon . . . . .	309
Reparation . . . . .	310
Treatment . . . . .	311
Displacement of Tendon . . . . .	312
Inflammation of Muscle . . . . .	312
Tumours . . . . .	313

## BURSÆ AND SHEATHS OF TENDONS.

CHAPTER XXI.—INFLAMMATION. GANGLION.	
Inflammation of Bursæ . . . . .	314
Of Bursæ Patellæ . . . . .	315
Bunion . . . . .	315
Tenosynovitis . . . . .	316
Ganglion . . . . .	317

## NERVES.

CHAPTER XXII.—INJURIES. NEURITIS. NEURALGIA.	
Injuries . . . . .	318
Neuritis . . . . .	318
Neuralgia . . . . .	319

## ARTERIES.

CHAPTER XXIII.—ANEURISM.	
Structural Conditions . . . . .	321
Circumscribed—True Aneurism . . . . .	321
Diffused—False Aneurism . . . . .	321
Fusiform or Tubular Aneurism . . . . .	321
Signs . . . . .	322
Diagnosis . . . . .	323
Causes . . . . .	323
Course and Terminations . . . . .	325
Spontaneous Cure . . . . .	325
Treatment . . . . .	328
Compression . . . . .	329
Ligature . . . . .	332
Manipulation . . . . .	339
Galvano-puncture . . . . .	340
Injection . . . . .	341
Treatment of Traumatic Aneurism . . . . .	342
Aneurismal Varix and Varicose Aneurism . . . . .	343
Signs . . . . .	344
Causes . . . . .	345
Treatment . . . . .	345

## CHAPTER XXIV.—ANEURISM OF SPECIAL ARTERIES.

Arch of Aorta . . . . .	347
Aneurisms at Root of Neck . . . . .	349
Treatment . . . . .	351
Innominate Aneurism . . . . .	351
Aneurisms of Right Carotid and Subclavian Arteries . . . . .	352
Carotid Aneurism . . . . .	352
Subclavian Aneurism . . . . .	353
Aneurism of Carotid Artery . . . . .	353
Wounds and Traumatic Aneurism . . . . .	355
Aneurismal Varix . . . . .	355
Aneurism of Internal Carotid . . . . .	355
Extra-cranial . . . . .	355
Intra-cranial . . . . .	355
Wounds, and Traumatic Aneurism of Internal or	
External Carotids . . . . .	358
Aneurism of Subclavian Artery . . . . .	358
Wounds and Traumatic Aneurism . . . . .	359
Aneurismal Varix . . . . .	359
Aneurism of Axillary Artery . . . . .	359
Wounds and Traumatic Aneurism . . . . .	360
Aneurisms of Brachial, Radial, and Ulnar Arteries . . . . .	360
Wounds and Traumatic Aneurism . . . . .	361
Aneurismal Varix, and Varicose Aneurism . . . . .	361
Aneurism of Abdominal Aorta . . . . .	362
Aneurisms of Iliac Arteries—Common, Internal, and	
External . . . . .	362
Aneurisms of Gluteal, Sciatic, and Pudic Arteries . . . . .	363
Wounds, and Traumatic Aneurism of Gluteal Artery . . . . .	363
Aneurism of Common Femoral Artery . . . . .	364
Wounds and Traumatic Aneurism . . . . .	365
Aneurismal Varix, and Varicose Aneurism . . . . .	365
Aneurism of Femoral Artery—Deep and Superficial	
Femorals . . . . .	365
Wounds and Traumatic Aneurism . . . . .	366
Aneurismal Varix, and Varicose Aneurism . . . . .	367
Aneurism of Popliteal Artery . . . . .	367
Wounds and Traumatic Aneurism . . . . .	369
Aneurisms of Tibial Arteries—Anterior and Posterior . . . . .	369
Aneurismal Varix, and Varicose Aneurism . . . . .	370

## CHAPTER XXV.—LIGATURE OF ARTERIES.

Ligature of an Artery in its continuity . . . . .	370
Ligature of an Artery at the seat of Wound . . . . .	372
Ligature of Innominate Artery . . . . .	372

LIGATURE OF ARTERIES—*continued.*

Surgical Anatomy . . . . .	372
Operation . . . . .	373
Ligature of the Common Carotid Artery . . . . .	374

CHAPTER XXXII.—INJURIES. SPRAINS. WOUNDS. DISLOCATIONS.	
Sprains or Strains . . . . .	506
Wounds . . . . .	506
Dislocations . . . . .	508
Signs . . . . .	508
Diagnosis . . . . .	509
Causes . . . . .	510
Reparation . . . . .	510
Treatment . . . . .	512
Compound Dislocation . . . . .	518
Treatment . . . . .	519
Amputation . . . . .	520
Complicated Dislocation . . . . .	521
Treatment . . . . .	522
Unreduced Dislocation and False Joint . . . . .	522
Treatment . . . . .	524
Congenital Dislocations . . . . .	526
CHAPTER XXXIII.—SPECIAL DISLOCATIONS.	
Dislocations of the Lower Jaw . . . . .	527
"     "     Spine . . . . .	529
"     "     Clavicle . . . . .	529
"     "     Scapula . . . . .	532
"     "     Shoulder-joint . . . . .	532
"     "     Sub-glenoid . . . . .	532
"     "     Sub-clavicular . . . . .	533
"     "     Sub-spinous . . . . .	533
"     "     Elbow-joint . . . . .	538
Radius and Ulna . . . . .	538
Ulna . . . . .	540
Radius . . . . .	541
"     "     Inferior Radio-Ulnar Articulation . . . . .	545
"     "     Radio-carpal Articulation . . . . .	546
"     "     Carpal Bones . . . . .	547
"     "     Metacarpal Bones . . . . .	548
"     "     Phalangeal Bones . . . . .	548
"     "     Pelvis . . . . .	550
"     "     Hip-joint . . . . .	551
On the Dorsum Ilii . . . . .	551
Into Great Ischiatic Notch . . . . .	551
Into Obturator Foramen . . . . .	556
Upon the Pubes . . . . .	558
Anomalous Dislocations . . . . .	559
"     "     Patella . . . . .	560
"     "     Knee-joint . . . . .	562

SPECIAL DISLOCATIONS—*continued*.

Dislocations of the Fibula . . . . .	566
"    "    Ankle-joint . . . . .	566
"    "    Astragalus . . . . .	569
"    "    other Tarsal Bones . . . . .	570
"    "    Metatarsal Bones . . . . .	571
"    "    Phalangeal Bones . . . . .	572

## CHAPTER XXXIV.—DISEASES OF JOINTS.

Synovitis . . . . .	572
Chronic Rheumatic Synovitis or Arthritis . . . . .	575
Scrofulous Synovitis . . . . .	577
Scrofulous Disease or Caries . . . . .	579
Ulceration of Articular Cartilages . . . . .	582
Anchylosis, or Stiff Joint . . . . .	584
Loose Cartilages . . . . .	586
Tumours . . . . .	587
Neuralgia . . . . .	588

## CHAPTER XXXV.—DISEASES OF PARTICULAR JOINTS.

Diseases of the Hip-joint . . . . .	588
Scrofulous Disease—Morbus Coxarius . . . . .	588
Chronic Rheumatic Arthritis—Morbus Coxæ Senilis . . . . .	592
Neuralgia . . . . .	592
Disease of the Sacro-iliac Joint . . . . .	592

## CHAPTER XXXVI.—DEFORMITIES.

Deformities of Face and Neck . . . . .	594
Wry-neck or Torticollis . . . . .	594
Strabismus or Squint . . . . .	596
Deformities of the Arm and Hand . . . . .	597
Deformities of the Leg . . . . .	598
Knock-knee . . . . .	598
Bowed or Bandied Legs . . . . .	599
Contraction of Knee-joint . . . . .	599
Talipes or Club-foot . . . . .	600
Talipes Equinus . . . . .	601
Talipes Varus . . . . .	602
Talipes Valgus . . . . .	604
Flat or Splay Foot . . . . .	604
Talipes Calcaneus . . . . .	605
Varieties of Club-foot . . . . .	605

CHAPTER XXXVII.—EXCISIONAL<sup>m</sup> SURGERY OF THE JOINTS  
AND BONES.

Of the Joints, for Disease . . . . .	606
Joint Excision, and the General Treatment of Joint- Disease . . . . .	607

EXCISIONAL SURGERY OF THE JOINTS—*continued.*

General Conditions of Disease for Excision . . . . .	608
Operation of Joint Excision . . . . .	610
Instruments, and General Directions . . . . .	610
After-treatment . . . . .	611
Repair after Excision . . . . .	613
Excision compared with Amputation . . . . .	613
"    "    "    Natural Cure by Anchylosis . . . . .	614
General Results . . . . .	614
Special Joints . . . . .	615
Knee-joint—Conditions for Excision . . . . .	615
Operation . . . . .	616
After-treatment . . . . .	619
Results—in relation to Natural Anchylosis . . . . .	620
"    "    Mortality . . . . .	620
Statistics, British and Foreign . . . . .	621
Hospitals of England and Scotland (Author's Collection) . . . . .	621

## SPECIAL PATHOLOGY AND SURGERY.

## DIVISION II.

## INJURIES AND DISEASES OF ORGANS AND REGIONS.

## THE HEAD.

	PAGE
CHAPTER XXXIX.—INJURIES AND DISEASES OF THE SCALP,	
CRANIUM, MEMBRANES OF THE BRAIN, AND BRAIN.	
Injuries of the Scalp . . . . .	713
Wounds . . . . .	713
Contusion . . . . .	714
Cephalhæmatoma . . . . .	714
Injuries of the Cranium . . . . .	714
Contusion of the Bone . . . . .	714
Fractures—of Vault of the Skull . . . . .	715
„ of Base of the Skull . . . . .	719
Injuries of the Membranes of the Brain. . . . .	721
Extravasation of Blood, within the Cranium . . . . .	721
Hernia Cerebri . . . . .	721
Injuries of the Brain . . . . .	722
Concussion . . . . .	722
Contusion . . . . .	724
Compression . . . . .	725
Wounds . . . . .	726
Injuries of the Cranial Nerves . . . . .	726
Traumatic Inflammation . . . . .	727
Abscess . . . . .	729
Trephining . . . . .	729
Tumours of the Head . . . . .	731
Cysts or Wens . . . . .	731
Vascular Tumours—Nævi . . . . .	731
Exostosis . . . . .	731
Fibrous or Fibro-cystic Tumour . . . . .	731
Myeloid Tumour . . . . .	731
Cancer . . . . .	731
Fungous Tumour of Dura Mater . . . . .	731
Congenital Hernial Tumours . . . . .	732
Hydrocephalus and Paracentesis Capitis . . . . .	732

## ORGANS OF SPECIAL SENSE, AND THEIR APPENDAGES.

CHAPTER XL.—OPHTHALMIC SURGERY, OR INJURIES AND  
DISEASES OF THE EYE AND ITS APPENDAGES.

Injuries . . . . .	733
Wounds—of Eyebrows and Eyelids . . . . .	733
„ of Eyeball . . . . .	733

OPHTHALMIC SURGERY—*continued.*

Contusion . . . . .	734
Foreign Bodies . . . . .	735
Diseases of Eyelids . . . . .	736
Hordeolum, or Styne . . . . .	736
Abscess in Meibomian Follicles . . . . .	736
Ophthalmia Tarsi . . . . .	736
Trichiasis . . . . .	737
Entropion . . . . .	737
Ectropion . . . . .	737
Epicanthus . . . . .	738
Ancyloblepharon . . . . .	738
Symblepharon . . . . .	738
Lagophthalmos . . . . .	738
Ptosis . . . . .	738
Spasmodic Twitching of Eyelid . . . . .	739
Hysterical Affections . . . . .	739
Tumours . . . . .	739
Lice . . . . .	739
Of Lachrymal Apparatus . . . . .	739
Tumours of Lachrymal Gland . . . . .	740
Lachrymal Obstructions—Epiphora . . . . .	740
Obstruction of Nasal Duct and Fistula Lachrymalis . . . . .	740
Dacryolithes . . . . .	742
Detached Eyelash . . . . .	742
Of the Conjunctiva . . . . .	742
Conjunctivitis, or Ophthalmia . . . . .	742
Catarrhal Ophthalmia . . . . .	743
Pustular Ophthalmia . . . . .	743
Purulent Ophthalmia . . . . .	743
"          "          in New-born Infants . . . . .	744
Gonorrhœal Ophthalmia . . . . .	745
Scrofulous Ophthalmia . . . . .	745
Granular Conjunctiva . . . . .	746
Growths of Conjunctiva . . . . .	746
Pterygium . . . . .	746
Pinguecula . . . . .	747
Tumours . . . . .	747
Cysticercus telæ Cellulosæ . . . . .	747
Nitrate of Silver Stains . . . . .	747
Of the Cornea . . . . .	747
Corneitis, or Keratitis . . . . .	747
Chronic Interstitial . . . . .	748
Opacities . . . . .	748
Ulcers . . . . .	748
Staphyloma . . . . .	749

OPHTHALMIC SURGERY—*continued.*

Conical Cornea . . . . .	749
Arcus Senilis . . . . .	749
Of the Sclerotic . . . . .	749
Sclerotitis—Rheumatic Ophthalmia . . . . .	749
Of the Iris . . . . .	751
Iritis . . . . .	751
Syphilitic Iritis . . . . .	751
Rheumatic Iritis . . . . .	752
Scrofulous Iritis . . . . .	752
Adhesions of Iris . . . . .	753
Staphyloma Scleroticæ . . . . .	753
Cysts of Iris . . . . .	753
Myosis and Mydriasis . . . . .	753
Artificial Pupil . . . . .	754
Of the Lens and Capsule . . . . .	755
Cataract . . . . .	755
Operations for . . . . .	757
On Infants . . . . .	761
Of the Choroid and Retina . . . . .	761
Choroiditis and Retinitis . . . . .	761
Dimness of Sight . . . . .	761
Defective Sight . . . . .	762
Impaired Vision . . . . .	762
Musæ Volitantes . . . . .	762
Amaurosis . . . . .	762
Ophthalmoscopic Appearances . . . . .	763
Ophthalmoscope . . . . .	765
Healthy appearance of Eye . . . . .	766
Glaucoma . . . . .	767
Iridectomy . . . . .	768
Short Sight—Myopia . . . . .	768
Long Sight—Presbyopia . . . . .	769
Colour-blindness—Acritochromacy . . . . .	769
Day sight—Hemeralopia . . . . .	769
Night sight—Nyctalopia . . . . .	769
Of the Eyeball, or of its Motor Apparatus . . . . .	769
Protrusion of Eyeball . . . . .	769
Dislocation . . . . .	770
Tumours . . . . .	770
Removal of Eyeball . . . . .	770
Strabismus or Squint . . . . .	771

## CHAPTER XLI.—INJURIES AND DISEASES OF THE EAR.

External Ear . . . . .	773
Wounds . . . . .	773

INJURIES AND DISEASES OF THE EAR—*continued*.

Foreign Bodies . . . . .	773
Displacement . . . . .	773
Hypertrophy . . . . .	774
Eczema . . . . .	774
Wax in Meatus . . . . .	775
Thickening of Cuticle . . . . .	775
Polypus . . . . .	775
Otorrhœa . . . . .	776
Fungous Granulations . . . . .	777
Internal Ear . . . . .	777
Otitis . . . . .	777
Artificial Membrana Tympani . . . . .	779
Collapse of . . . . .	779
Eustachian Tubes—Throat Deafness . . . . .	779
Ear-ache—Otalgia . . . . .	780
Deafness . . . . .	780

## CHAPTER XLII.—INJURIES AND DISEASES OF THE NOSE.

Foreign Bodies . . . . .	781
Epistaxis . . . . .	781
Hypertrophy or Lipoma . . . . .	783
Cancer . . . . .	783
Lupus . . . . .	783
Syphilitic Ulcer . . . . .	784
Ozæna or Rhinorrhœa . . . . .	784
Thickening of Schneiderian Membrane . . . . .	785
Polypus . . . . .	786
Gelatinous or Mucous . . . . .	786
Fibrous . . . . .	788
Cancerous . . . . .	788
Tumours of Septum . . . . .	788
Calculi or Rhinoliths . . . . .	791
Plastic Surgery of Nose—Rhino-plastic Operations . . . . .	791

## CHAPTER XLIII.—INJURIES AND DISEASES OF THE MOUTH.

Lips—Wounds . . . . .	795
Hare-lip . . . . .	795
Congenital Transverse Fissures of Cheeks . . . . .	798
Congenital Contraction of Mouth . . . . .	798
Cheiloplastic Operations . . . . .	798
of Lower Lip . . . . .	798
of Upper Lip . . . . .	799
Diseases—Hypertrophy . . . . .	798
Ulceration . . . . .	799

INJURIES AND DISEASES OF THE MOUTH—*continued.*

Tumours . . . . .	799
Encysted . . . . .	800
Erectile . . . . .	800
Epithelial Cancer . . . . .	801
Cheeks—Wounds, and Salivary Fistula . . . . .	801
Tumours . . . . .	801
Corroding Ulcers . . . . .	802
Cancerum Oris . . . . .	802
Tongue—Wounds . . . . .	803
Foreign Bodies . . . . .	803
Tongue-tie . . . . .	803
Prolapsus . . . . .	804
Glossitis . . . . .	804
Tumours—Cancer . . . . .	807
Erectile . . . . .	807
Fatty . . . . .	807
Ranula . . . . .	807
Cysts . . . . .	808
Gums and Teeth—Diseases . . . . .	808
Alveolar Abscess—Gum-boil or Parulis . . . . .	809
Epulis . . . . .	809
Congenital Hypertrophy of Gum . . . . .	810
Polypus . . . . .	810
Vascular Tumours . . . . .	811
Teeth—Injuries and Misplacements . . . . .	811
Eruption of Milk-teeth . . . . .	811
Mal-eruption of Wisdom Teeth . . . . .	811
Irregularities of Permanent Teeth . . . . .	811
Diseases—Caries and Necrosis . . . . .	811
Hæmorrhage after Tooth-extraction . . . . .	813

## CHAPTER XLIV.—DISEASES OF THE JAWS.

Cleft-palate . . . . .	814
Staphyloraphy—Operation of . . . . .	814
Necrosis of Jaws . . . . .	817
Abscess of Antrum . . . . .	818
Dropsy of Antrum . . . . .	819
Tumours . . . . .	820
of Upper Jaw . . . . .	820
of Lower Jaw . . . . .	821
Excision of Upper Jaw . . . . .	822
„ Lower Jaw . . . . .	824
Closure of the Jaws . . . . .	826
Excision of Articulation . . . . .	827

## THE NECK.

CHAPTER XLV.—INJURIES OF LARYNX AND TRACHEA, PHARYNX, AND ŒSOPHAGUS. PAGE

Wounds of the Throat—Cut-throat . . . . .	827
Foreign Bodies in the Air-passages . . . . .	830
Scalds of the Glottis, Mouth, and Pharynx . . . . .	832
Asphyxia or Apnoea . . . . .	832
Artificial Respiration . . . . .	835
Foreign Bodies . . . . .	836
Pharyngotomy and Œsophagotomy . . . . .	838

## CHAPTER XLVI.—DISEASES OF PHARYNX AND ŒSOPHAGUS, LARYNX, AND TRACHEA.

Tonsillitis . . . . .	838
Chronic Enlargement of Tonsils . . . . .	839
Elongation or Relaxation of Uvula . . . . .	840
Tumours of Velum Palati . . . . .	841
Pharyngitis . . . . .	841
Tumours of the Pharynx . . . . .	842
Stricture of Œsophagus . . . . .	842
Gastrotomy . . . . .	843
Paralysis of Œsophagus . . . . .	844
Dilatation and Sacculation . . . . .	844
Use of Stomach-pump . . . . .	844
Laryngitis . . . . .	845
Laryngoscope . . . . .	845
Laryngoscopy . . . . .	846
Treatment of Laryngeal Affections . . . . .	847
Laryngotomy and Tracheotomy . . . . .	848

## CHAPTER XLVII.—DISEASES OF THE THYROID GLAND. THE PAROTID GLAND. TUMOURS OF THE NECK.

## Thyroid Gland.

Bronchocele or Goitre . . . . .	850
Inflammation of Thyroid Gland . . . . .	853
Fibrous, Cartilaginous, and Osseous Formations.	
Tubercle. Cancer . . . . .	853
Hernia Bronchialis . . . . .	853

## Parotid Gland.

Parotitis or Mumps . . . . .	853
Glandular Parotid Tumour . . . . .	853
Tumours in Parotid Region . . . . .	854

## Tumours of the Neck.

Enlargement of Cervical Glands . . . . .	855
Induration of the Sterno-mastoid Muscle . . . . .	855

DISEASES OF THE THYROID, &c.—*continued*.

Enlarged Bursæ . . . . .	855
Cysts . . . . .	855
Fatty, and other Tumours . . . . .	856

## CHAPTER XLVIII.—INJURIES AND DISEASES OF THE SPINE.

Anatomy and Physiology of Spine or Vertebral Column . . . . .	856
Wounds . . . . .	857
Sprains . . . . .	857
Intra-spinal Hæmorrhage . . . . .	858
Inflammation of Joints of Spine . . . . .	858
Fractures . . . . .	859
Dislocation . . . . .	859
Concussion of Spinal Cord . . . . .	861
Spinal Meningitis . . . . .	862
Spinal Myelitis . . . . .	862
Compression of Spinal Cord . . . . .	867
Disease of the Spine . . . . .	867
Psoas Abscess . . . . .	869
Varieties of Spinal Abscess . . . . .	870
Disease of Atlas and Axis . . . . .	872
Lateral Curvature . . . . .	873
Posterior Curvatures—Cyphosis and Lordosis . . . . .	880
Spina Bifida . . . . .	881

## THE THORAX.

## CHAPTER XLIX.—INJURIES OF THORACIC PARIETES, AND ORGANS.

Wounds of Parietes of Chest . . . . .	882
Wounds involving Thoracic Organs . . . . .	882
Hernia of Lung or Pneumatocele . . . . .	886
Pneumothorax . . . . .	886
Emphysema . . . . .	886
Hæmothorax . . . . .	887
Hydrothorax . . . . .	887
Empyema . . . . .	888
Paracentesis Thoracis . . . . .	888
Hydrops Pericardii . . . . .	889
Deformity of Chest . . . . .	889

## CHAPTER L.—DISEASES OF THE BREAST.

Physiological and Anatomical Relations of Mammary Gland . . . . .	890
General Pathology and Diagnosis . . . . .	891
Method of Examining the Breast . . . . .	891
Inflammation, or Mastitis . . . . .	892
Scrofulous Enlargement . . . . .	893

DISEASES OF THE BREAST—*continued.*

	PAGE
Inflammation of Nipple . . . . .	893
Chronic Induration . . . . .	894
Irritable Mamma . . . . .	894
Hypertrophy . . . . .	894
Atrophy . . . . .	895
Tumours . . . . .	895
Adenocoele or Adenoid Tumour . . . . .	895
Fibrous Tumour—Neuroma . . . . .	897
Fatty Tumour . . . . .	897
Cartilaginous and Osteoid Tumours . . . . .	897
Cysts and Cystic Tumours . . . . .	898
Cancer—Scirrhus . . . . .	899
Encephaloid . . . . .	900
Colloid . . . . .	901
Recurrent Cancer . . . . .	904
Amputation of Breast . . . . .	904
Functional Disorders of Breast . . . . .	906
Abnormal Secretion of Milk . . . . .	906
Excessive Lacteal Secretion, or Galactorrhœa . . . . .	906
Deficient Lacteal Secretion, or Agalactia . . . . .	906
Congestion with Milk . . . . .	906
Diseases of Male Breast . . . . .	906
Anomalies of Development . . . . .	907
Absence of Breast . . . . .	907
Supernumerary Breasts or Nipples . . . . .	907

## THE ABDOMEN.

## CHAPTER LI.—INJURIES OF ABDOMINAL PARIETES, AND VISCERA.

Contusion . . . . .	907
Wounds of Parietes . . . . .	908
Injuries implicating Viscera . . . . .	908
Rupture or Penetrating Wound . . . . .	908
Protrusion . . . . .	909
Traumatic Peritonitis . . . . .	912

## CHAPTER LII.—HERNIA.

General Pathology of Abdominal Hernia . . . . .	913
Situations of Herniæ . . . . .	917
Names of Herniæ . . . . .	917
Causes . . . . .	918
Reducible Hernia . . . . .	919
Treatment—Taxis . . . . .	920
Radical Cure—Operations for . . . . .	921
Irreducible Hernia . . . . .	921

HERNIA—*continued*.

Treatment . . . . .	922
Incarcerated . . . . .	922
Strangulated . . . . .	923
Diagnosis . . . . .	924
Operation—Herniotomy . . . . .	928
Results . . . . .	935
Artificial Anus . . . . .	935
Double Hernia . . . . .	937

## CHAPTER LIII.—SPECIAL HERNIE.

Inguinal Hernia . . . . .	938
Oblique Inguinal Hernia . . . . .	938
Anatomy . . . . .	939
Seat of Stricture . . . . .	940
Direct Inguinal Hernia . . . . .	940
Anatomy . . . . .	940
Seat of Stricture . . . . .	941
Signs of Inguinal Hernia . . . . .	941
Congenital Hernia . . . . .	942
Infantile or Encysted Hernia . . . . .	944
Diagnosis of Inguinal Hernia . . . . .	945
Treatment . . . . .	948
Reducible, and Trusses . . . . .	948
Radical Cure. Operations . . . . .	950
Irreducible . . . . .	957
Strangulated. Operation . . . . .	957
Congenital Hernia . . . . .	958
Infantile or Encysted . . . . .	959
Femoral or Crural Hernia . . . . .	959
Anatomy . . . . .	960
Seat of Stricture . . . . .	962
Varieties . . . . .	962
Signs and Diagnosis. . . . .	963
Treatment . . . . .	965
Reducible, and Trusses . . . . .	965
Radical Cure. Operation . . . . .	965
Irreducible . . . . .	967
Strangulated. Operation . . . . .	967
Umbilical Hernia . . . . .	970
Anatomy . . . . .	970
Seat of Stricture . . . . .	971
Signs . . . . .	971
Treatment . . . . .	972
Reducible, and Trusses . . . . .	972

	PAGE
SPECIAL HERNIA— <i>continued.</i>	
Irreducible . . . . .	973
Strangulated. Operation . . . . .	973
Ventral Hernia . . . . .	973
Lumbar Hernia . . . . .	974
Obturator or Thyroid Hernia . . . . .	974
Perinæal Hernia . . . . .	975
Vaginal Hernia . . . . .	975
Pudendal Hernia . . . . .	975
Ischiatic Hernia . . . . .	976
Diaphragmatic Hernia . . . . .	976
CHAPTER LIV.—INTESTINAL OBSTRUCTION.	
Intestinal Conditions or Causes . . . . .	977
Symptoms and Diagnosis . . . . .	978
Treatment . . . . .	979
Gastrotomy . . . . .	981
Colotomy . . . . .	982
CHAPTER LV.—PARACENTESIS ABDOMINIS.	
Operation of Tapping Abdomen . . . . .	983
CHAPTER LVI.—DISEASES, INJURIES, AND MALFORMATIONS OF RECTUM AND ANUS.	
Diseases . . . . .	985
Inflammation and Rectal Abscess . . . . .	985
Fistula in Ano . . . . .	986
Ulcer of Rectum, and Fissure of Anus . . . . .	991
Hæmorrhoids—External and Internal . . . . .	993
Prolapsus of Rectum . . . . .	1002
Polypus of Rectum . . . . .	1005
Stricture of Rectum . . . . .	1007
Rectal Fistula . . . . .	1010
Recto-Vesical . . . . .	1010
Recto-Vaginal . . . . .	1011
Anal Tumours . . . . .	1012
Anal Contraction . . . . .	1012
Injuries . . . . .	1012
Wounds . . . . .	1012
Foreign Bodies . . . . .	1013
Congenital Malformations . . . . .	1014
Imperforate Anus . . . . .	1014
Imperforate Rectum . . . . .	1014
Rectal Communications with Bladder, Vagina, Pe- rinæum . . . . .	1016

DISEASES, INJURIES, &c.—*continued.*

Functional Disorders . . . . .	1017
Atony of Rectum . . . . .	1017
Irritable Rectum, or Sphincter . . . . .	1017
Neuralgia of Rectum, or Anus . . . . .	1018
Pruritus Ani . . . . .	1018

## THE GENITO-URINARY ORGANS.

CHAPTER LVII.—INJURIES AND DISEASES OF THE BLADDER—  
AND URINARY CALCULUS.

Injuries . . . . .	1019
Laceration and Rupture of Bladder . . . . .	1020
Rupture of Ureter . . . . .	1020
Foreign Bodies . . . . .	1020
Urinary Calculus . . . . .	1021
Origin and Production . . . . .	1021
Physical Properties . . . . .	1022
Structure . . . . .	1022
Chemical Composition . . . . .	1023
Relative frequency of different Calculi . . . . .	1023
Uric or Lithic Acid Calculus . . . . .	1024
Tests . . . . .	1024
Urate of Ammonia Calculus . . . . .	1024
Tests . . . . .	1024
Urates of Soda or Lime . . . . .	1024
Uric or Xanthic Oxide . . . . .	1024
Tests . . . . .	1024
Cystic Oxide or Cystine Calculus . . . . .	1024
Tests . . . . .	1025
Fibrinous Calculus . . . . .	1025
Tests . . . . .	1025
Uro-Stealith Calculus . . . . .	1025
Tests . . . . .	1025
Blood Calculus . . . . .	1025
Tests . . . . .	1025
Carbonate of Lime Calculus . . . . .	1025
Tests . . . . .	1025
Oxalate of Lime Calculus . . . . .	1026
Varieties . . . . .	1026
Tests . . . . .	1026
Phosphate of Ammonia and Magnesia-Triple Phos- phate Calculus . . . . .	1026
Tests . . . . .	1026
Phosphate of Lime . . . . .	1026
Tests . . . . .	1026

INJURIES AND DISEASES OF THE BLADDER—*continued.*

Phosphate of Lime, and Phosphate of Magnesia and Ammonia—Mixed Phosphates—Fusible Calculus . . . . .	1027
Tests . . . . .	1027
Silicious Calculus . . . . .	1027
Tests . . . . .	1027
Chemical Examination of Calculi . . . . .	1027
Appliances and Tests . . . . .	1027
Order of Examination . . . . .	1027
Table for Examining Urinary Calculi . . . . .	1028
Causes of Urinary Calculi . . . . .	1029
Climate and Locality . . . . .	1029
Hereditary tendency . . . . .	1029
Sex . . . . .	1029
Period of Life or Age . . . . .	1029
Habits of Life . . . . .	1029
Morbid conditions of Urinary Organs . . . . .	1030
Renal Calculus . . . . .	1030
Treatment . . . . .	1030
Stone in the Bladder . . . . .	1031
Symptoms, and Sounding the Bladder . . . . .	1031
Encysted Calculus . . . . .	1034
Diagnosis . . . . .	1034
Consequences and Terminations . . . . .	1035
Treatment . . . . .	1036
Operations . . . . .	1036
Lithotomy . . . . .	1036
Lateral Operation . . . . .	1037
Cutting on a Straight Staff . . . . .	1044
In Children . . . . .	1046
Anatomical Peculiarities . . . . .	1046
Difficulties and Accidents . . . . .	1048
In Adults . . . . .	1048
In Children . . . . .	1048
After-treatment . . . . .	1052
Consequences . . . . .	1052
Causes of Death, and Results . . . . .	1053
Recurrence of Stone . . . . .	1054
Median Lithotomy . . . . .	1055
The Old Marian Operation . . . . .	1055
Allarton's Operation . . . . .	1055
Compared with Lateral Operation . . . . .	1056
Results . . . . .	1056

	PAGE
INJURIES AND DISEASES OF THE BLADDER— <i>continued.</i>	
Rectangular Staff Operation . . . . .	1056
Comparative estimate of . . . . .	1056
Bilateral Lithotomy . . . . .	1056
Results . . . . .	1057
Medio-bilateral Operation . . . . .	1057
Quadrilateral Section of Prostate . . . . .	1057
Recto-vesical Operation . . . . .	1057
Comparative estimate of . . . . .	1057
Results . . . . .	1057
Supra-Pubic—Hypo-gastric, or High Operation . . . . .	1057
Compared with Lateral Operation . . . . .	1057
Results . . . . .	1058
Lithotritry . . . . .	1058
After-treatment . . . . .	1063
Difficulties and Dangers . . . . .	1064
Results, and as compared with Lithotomy . . . . .	1065
Selection of Lithotomy, or Lithotritry . . . . .	1065
Conditions determining Selection . . . . .	1065
Recurrence of Stone . . . . .	1068
Treatment . . . . .	1068
Calculus in the Female . . . . .	1068
Symptoms . . . . .	1069
Treatment . . . . .	1069
Operations . . . . .	1069
Dilatation of Urethra . . . . .	1069
Dilatation, with partial slitting up . . . . .	1069
Double incision . . . . .	1070
Lithotritry . . . . .	1070
Lithotomy . . . . .	1070
Urethral . . . . .	1070
Direct . . . . .	1070
Vagino-vesical . . . . .	1070
Supra-pubic . . . . .	1071
Solution of Stone in Bladder . . . . .	1071
Electrolysis . . . . .	1071
CHAPTER LVIII.—DISEASES OF THE BLADDER.	
Cystitis—acute . . . . .	1072
Chronic . . . . .	1073
Tumours . . . . .	1074
Fibrous—Warty—Polypoid . . . . .	1074
Villous, or Vascular . . . . .	1075
Cancer . . . . .	1075
Tubercle . . . . .	1076

DISEASES OF THE BLADDER—*continued.*

Hæmaturia . . . . .	1076
Causes . . . . .	1076
Treatment . . . . .	1077
Malformations . . . . .	1077
Absence, with communications of Ureters—Urethral,	
Rectal, Vaginal . . . . .	1077
Two or more Bladders . . . . .	1077
Extroversion of Bladder . . . . .	1077
Operations . . . . .	1078
Wood's Operation . . . . .	1078
After-treatment . . . . .	1079
Results . . . . .	1079
Functional Morbid Conditions . . . . .	1079
Irritability of the Bladder . . . . .	1080
Spasm . . . . .	1082
Neuralgia . . . . .	1082
Paralysis . . . . .	1082
Atony, from over-distension . . . . .	1083
Frequent Micturition . . . . .	1083
Incontinence of Urine . . . . .	1083
Engorgement and Overflow . . . . .	1084
Retention of Urine . . . . .	1084

## CHAPTER LIX.—DISEASES OF THE PROSTATE.

Inflammation—Prostatitis . . . . .	1085
Abscess . . . . .	1085
Chronic Enlargement . . . . .	1086
Atrophy . . . . .	1093
Cancer . . . . .	1093
Cysts . . . . .	1094
Tubercle . . . . .	1094
Prostatic Calculus . . . . .	1094

## CHAPTER LX.—DISEASES OF THE URETHRA.

Inflammation—Urethritis . . . . .	1095
Gonorrhœa—Blennorrhagia . . . . .	1096
Gleet . . . . .	1098
Complications . . . . .	1099
Consequences . . . . .	1100
Gonorrhœa in the Female . . . . .	1102
Stricture . . . . .	1103
Organic or Permanent Stricture . . . . .	1103
Situation . . . . .	1103
Symptoms . . . . .	1104

DISEASES OF THE URETHRA—*continued*.

Varieties . . . . .	1105
Causes . . . . .	1107
Consequences and Terminations . . . . .	1108
Treatment . . . . .	1109
Gradual Dilatation . . . . .	1109
Difficulties and Accidents . . . . .	1111
Immediate and Forcible Dilatation or Rupture . . . . .	1112
Results . . . . .	1113
Caustics . . . . .	1114
Division of Stricture . . . . .	1114
Internal Urethrotomy . . . . .	1114
Results . . . . .	1115
External Urethrotomy . . . . .	1115
Perinæal Section . . . . .	1115
Results . . . . .	1116
Spasmodic Stricture . . . . .	1117
Inflammatory Stricture . . . . .	1118
Tumours in Urethra . . . . .	1118
Urethral Calculus . . . . .	1119
Retention of Urine . . . . .	1120
Causes . . . . .	1120
Consequences . . . . .	1120
Treatment . . . . .	1120
Catheterism . . . . .	1120
Incision of Urethra . . . . .	1121
Puncture of Bladder through Rectum . . . . .	1121
Above Pubes . . . . .	1122
Through Symphysis Pubis . . . . .	1122
Extravasation of Urine . . . . .	1123
Rupture of Bladder . . . . .	1124
Urinary Abscess . . . . .	1124
Urinary Fistula . . . . .	1125
Varieties . . . . .	1125
Urethro-plastic Operations . . . . .	1126
Urinary-Vaginal, and Uterine Fistula . . . . .	1127
Operations . . . . .	1127

## CHAPTER LXI.—INJURIES AND DISEASES OF PENIS.

Injuries . . . . .	1129
Wounds, and Laceration . . . . .	1129
Hæmorrhage . . . . .	1129
Wound of Urethra . . . . .	1129
Diseases . . . . .	1130
Balanitis and Posthitis . . . . .	1130

INJURIES AND DISEASES OF PENIS—*continued*.

Phymosis . . . . .	1131
Congenital . . . . .	1131
Circumcision . . . . .	1132
Paraphymosis . . . . .	1132
Gangrene of Prepuce . . . . .	1133
Hypertrophy of Prepuce . . . . .	1133
Warts . . . . .	1133
Cancer of Penis . . . . .	1133
Scirrhus, and Epithelial . . . . .	1134
Amputation of Penis . . . . .	1134
Tumours—non-malignant . . . . .	1135
Malformations . . . . .	1135
Deficiency of Urethra . . . . .	1135
Hypospadias . . . . .	1135
Epispadias . . . . .	1135
Absence of Urethra . . . . .	1135

CHAPTER LXII.—DISEASES OF THE SCROTUM, TESTIS, AND  
CORD.

Diseases of Scrotum . . . . .	1136
Inflammatory Œdema . . . . .	1136
Anasarca . . . . .	1136
Œdema in New-born Infants . . . . .	1136
Elephantiasis or Hypertrophy . . . . .	1136
Excision, and Results . . . . .	1137
Tumours . . . . .	1137
Fibrous Tumour . . . . .	1137
Epithelial or Soot-Cancer . . . . .	1137
Diseases of Testis and Cord . . . . .	1138
Hydrocele . . . . .	1138
Hydrocele of Tunica Vaginalis . . . . .	1139
Varieties of Hydrocele . . . . .	1140
Congenital Hydrocele . . . . .	1143
Encysted Hydrocele . . . . .	1143
Hydrocele of Spermatic Cord . . . . .	1144
Hæmatocele . . . . .	1144
Hæmatocele of Tunica Vaginalis . . . . .	1145
Encysted Hæmatocele of the Testis or Cord . . . . .	1146
Varicocele . . . . .	1146
Orchitis, and Epididymitis . . . . .	1149
Chronic Enlargement . . . . .	1151
Syphilitic Sarcocoele . . . . .	1151
Scrofulous Sarcocoele . . . . .	1152

DISEASES OF THE SCROTUM, TESTIS, AND CORD—*continued*.

Abscess in Testicle . . . . .	1153
Hernia Testis . . . . .	1153
Tumours . . . . .	1153
Cystic Tumour . . . . .	1153
Varieties . . . . .	1154
Fibrous Tumour . . . . .	1155
Cartilaginous Tumour—Enchondroma . . . . .	1155
Cancer . . . . .	1155
Encephaloid . . . . .	1155
Scirrhus . . . . .	1155
Castration, and Results . . . . .	1157
Atrophy of Testicle . . . . .	1158
Functional Disorders . . . . .	1158
Spermatorrhœa . . . . .	1158
Impotence . . . . .	1161
Congenital . . . . .	1161
Neuralgia of Testicle . . . . .	1162
Malposition of Testicle. Congenital . . . . .	1162
Diseases of Retained Testicle . . . . .	1163
Mis-descent of Testicle . . . . .	1163
Inversion of Undescended Testicle . . . . .	1163
Diseases of Vesiculæ Seminales . . . . .	1163

## CHAPTER LXIII.—DISEASES OF FEMALE GENITAL ORGANS.

External Organs . . . . .	1164
Wounds of Vulva, or of Vagina . . . . .	1164
Laceration of Perinæum . . . . .	1164
Foreign Bodies in Vagina . . . . .	1166
Diseases—Hypertrophy of Labia, or of Clitoris . . . . .	1166
Condylomata or Verruæ . . . . .	1166
Abscess of Labium . . . . .	1167
Cystic Tumours . . . . .	1167
Epithelial Cancer . . . . .	1167
Rodent Ulcer . . . . .	1167
Erectile Tumour . . . . .	1167
Closure of Labiæ, or of Vagina . . . . .	1168
Imperforate Hymen . . . . .	1168
Rectal and Vaginal Fistulæ . . . . .	1169
Prolapsus Vaginæ . . . . .	1169
Tumours . . . . .	1169
Uterus . . . . .	1169
Displacements . . . . .	1169
Prolapsus and Procidentia . . . . .	1169

DISEASES OF FEMALE GENITAL ORGANS—*continued.*

Tumours . . . . .	1170
Fibrous . . . . .	1170
Polypi . . . . .	1172
Cancer . . . . .	1173
Absence of Uterus, and Ovaries . . . . .	1174
Ovaries . . . . .	1174
Tumours . . . . .	1174
Fibrous. Cancerous . . . . .	1174
Cystic, and Ovarian Dropsy . . . . .	1174
Treatment . . . . .	1176
Tapping . . . . .	1176
Obliteration by Injection . . . . .	1176
Ovariectomy . . . . .	1177
Conditions for Operation . . . . .	1177
Operation . . . . .	1179
After-treatment . . . . .	1181
Results . . . . .	1181

SURGERY.

---

SURGERY is that primary division of Medicine, which has for its object the cure or the relief of morbid conditions of the body, in a corresponding division of Pathology. But the line of separation is arbitrary, conventional, and indefinite.

*Firstly*, as to the nature of the morbid conditions, or Surgical Pathology. All injuries, malformations, and deformities, congenital and acquired, and all diseases affecting external parts, are usually allotted to Surgery.

*Secondly*, in respect to the kind of Treatment, or the means of cure or relief. Surgery comprises all operations effected by instruments, manipulative procedures, and the employment of mechanical appliances; but it also has recourse to the administration of medicinal agents, and of hygienic measures.

Surgical Pathology is both General and Special. *General* Surgical Pathology comprises the different forms of Injury and Disease which are common to all parts of the body; and these morbid conditions, illustrating the laws of Pathology, are the primary source of guidance in all surgical practice.

As general forms of Injury—Wounds, Fractures, Dislocations, and Aneurisms, are naturally associated; and in virtue of the various laws whereby these lesions undergo Reparation, through processes which are more or less clearly referable to modifications of healthy Nutrition. But this department will be more conveniently considered in connexion with the particular Textures injured. Inflammation, Morbid Growths or Tumours, and Degenerations, may also be referred to modifications of Nutrition; namely, to Accelerated, to Reproductive, and to Declining Nutrition. Certain Blood-diseases, Contagious diseases, and general diseases of the Nervous System, further illustrate the laws of Pathology and Physiology.

*Special* Surgical Pathology may be subdivided into injuries and diseases of the Textures and Textural Systems—*e.g.*, the Skin and the Vascular System, and those which, with malformations, pertain to Organs and Regions—*e.g.*, the Organs of Special Sense, and of Reproduction. The latter subdivision, as a mode of classification, makes no pretension to any scientific distinctions; it is simply an anatomical or a topographical arrangement of morbid conditions.

The pathology of injuries and diseases, taken individually, embraces : (1) the particular structural condition presented, its signs and symptoms, and its diagnosis or detection and discrimination from other conditions; (2) its cause or causes, or etiology, and the effects of the morbid condition itself as a cause; (3) its course, terminations, and consequences, and the prognosis or foreknowledge of these events.

The treatment in any case may be operative, or medicinal, or both.

If in addition to the laws of Pathology, the guiding elements be selected in describing each form of Injury and Disease, and general Principles be established which shall govern its diagnosis, etiology, prognosis, and treatment, the whole of this guiding knowledge will constitute the SCIENCE of Surgery. The Principles here alluded to, form the design of my "Principles of Surgery"; and references, for the convenience of those who have that work, are made thereto, in the course of this volume. Such references are denoted by P., with the page, in brackets; as thus, [P. p. ]. But the two works are quite independently complete, each of the other.

Regarded as an ART, Surgery may, like most other Arts, be practised in either of two ways: Empirically, by experience alone, or as a Scientific Art, by the guidance of the Science pertaining to it. In other words, there may be an empirical, or a scientific practice of diagnosis, etiological investigation, prognosis, and treatment; according as these branches of inquiry have, or have not, a dependence on guiding pathological knowledge and principles. The Practice of Surgery, as a Scientific Art, might, in a restricted sense, have regard only to treatment, and this has been exclusively or principally its signification—Rules of Treatment having been designated the Principles of Surgery; but in its more extended meaning, the Art would also have reference to the application of Principles in the other, and preparatory, branches of inquiry.

The relative importance of these three aspects of inquiry respecting morbid conditions, as to their nature, causes, courses and terminations, and of the whole of this pathological knowledge in relation to treatment, may be briefly estimated as follows.

1. *Diagnosis* is primarily necessary, in order to discover the particular structural condition, situation, and extent of the injury or disease, when capable of being so defined, and its distinction from other conditions.

To make this discovery, the concomitant effects of the morbid condition are taken as *Signs* or *Symptoms* of its existence. The relative value of such evidence will depend upon, and vary with, its more or less constant and exclusive conjunction with the morbid condition. Accordingly, a Symptom, or as the etymological meaning of this term would express, a coincidence or co-occurrence, is less characteristic and distinctive than a Sign, the latter being that by which anything is known or recognised. Any sign peculiar to a morbid condition is named *pathognomonic*.

The earliest and most exact source of diagnosis is Pathological Anatomy, as directly manifesting during life the essential nature of the morbid condition, by the physical, the structural, or the chemical changes which the part affected undergoes.

Diagnosis may be corroborated by Pathology—i.e., the functional disturbances accompanying the particular disease or injury; also by connecting the morbid condition with its external cause, and by the characteristic effects of the therapeutic measures employed.

For example, the fact of an individual having been exposed to

malaria, is evidence presumptive that he may have ague; whilst the fact of his disease disappearing by the administration of quinine alone, is, among *other* evidence, corroborative of that disease being ague.

But the diagnostic value of all such *circumstantial* evidence is regulated by its more or less *constant* and *exclusive* association with the disease or injury which is sought to be identified.

Viewed in this light, the evidence of Pathology—functional disturbances—of external causes, and the effects of therapeutic measures, possess different degrees of diagnostic value; but the assurances derived from all these resources are, at the best, equivocal, and therefore misleading. Here it is that Pathological Anatomy, applied during life—Clinical Pathological Anatomy—comes to our aid.

By an appeal to the “physical” properties of organs and textures, as discovered *during life*, we can *partly* corroborate or rectify our interpretation of mere functional symptoms.

By the “structural” character of morbid products and secretions discharged from the natural passages—as the mouth, œsophagus, stomach, and intestines; the lungs, urinary bladder, kidneys, uterus, and vagina; those also which are externally yielded by or through the skin, or procured by puncture, as from tumours; possibly, in some cases, by “chemical” analysis of some such materials; we gain *direct* insight into, and evidence respecting, the structural conditions of *most* internal organs and of morbid products issuing from them.

Such application of Pathological Anatomy, therefore, directly indicates the *exact* structural condition, the situation, and even the extent, of the disease; and by virtue of this qualification, as a method of diagnosis, is more trustworthy than the evidence of Pathology, or any other collateral testimony.

The superiority of physical diagnosis, by virtue of the *earliness* with which the physical characters of a disease become obvious during life, is impaired by its inferiority in respect of *exactitude*, as compared with structural diagnosis.

Duly weighing all these considerations, we arrive at this conclusion—that it is only by careful and repeated clinical observation of the “physical,” the “structural,” and, if possible, the “chemical” conditions—which taken *collectively*, are the *constant* signs of disease; by a similar observation of any collateral *circumstances* of evidence—*i.e.*, alterations of function; precurrence of external causes, and the effects of therapeutic measures; and by connecting *all* this evidence during life, with certain pathologico-anatomical alterations, as demonstrated by the scalpel, the microscope, and possibly, by chemical analysis after death—that we can rationally hope to establish the *earliest* and *most exact* diagnosis.

This connexion, oft-recurring, at length begets self-confidence; so that with the accumulation of such experience our diagnosis, although determined during life, and therefore by evidence not infallible, yet having been repeatedly verified by *post-mortem* examination, now supplies a proportionately sure *basis* for Therapeutics.

2. *Etiology* comprises the knowledge of causes, and their operation, in the production of injury or disease. Such causes may be *external* to the body, as external violence in the production of injury, or exposure to cold in inducing disease; or, they may be *internal*, by the excess, deficiency, or perversion, of structure and function. Both classes of causes may be either *predisposing*, or *immediate* and exciting, in their opera-

tion. Sometimes, the former occurs after the latter mode of causation, as when an individual undergoes fatigue or privation, after exposure to an infectious poison. Then, that weakening of the system cannot be said to predispose, but it is aptly named the *determining* cause.

An innate power of resisting the supervention of morbid conditions, explains why the same cause does not invariably produce its reputed effect in different individuals, or in the same individual, at different periods of life; this uncertainty being due to different degrees of resisting power. But the influence of habitual toleration will also much affect the operation of causes, whether external or internal.

Either kind of cause may be self-sufficient, but both kinds frequently co-operate, or operate in succession; the internal cause more commonly predisposing, the external, when sufficiently aided thereby, immediately inducing disease, or, occasionally, injury. Thus, a fall which does not produce a hernial protrusion in one case, immediately does so in another, owing to weakness of the abdominal wall at the seat of rupture, as the structural predisposing condition to this lesion; and a posture which does not cause an apoplectic seizure in one case, immediately does so in another, owing to the blood-vessels of the brain having become brittle from calcareous degeneration.

Causes are also distinguished as *local* and *constitutional*. The former term requires no definition; the latter signifies such conditions of disease as have a systemic character, and a correspondingly widespread influence, in the production of local manifestations. Such are principally diseases of the blood, of the nervous system, or of nutrition. Local causes may give rise to constitutional diseases; and conversely, any constitutional cause must give rise to, and be manifested by, some local affection or affections. Thus we speak often of the constitutional origin of local disease, a general and most important doctrine of etiology, originally taught by Abernethy.

The detection of internal causes, whether local or constitutional, may be regarded as an extension of diagnosis, and consequently pertains chiefly to Clinical Pathological Anatomy; but the operation of these causes, through functional disturbances, comprises the study of Pathology.

3. *Prognosis*, or foreknowledge of the course and terminations of injuries and diseases, implies their continued functional disturbances, and as such an enlarged study of Pathology.

4. *Treatment* derives its Indications from each of the three foregoing heads of inquiry respecting morbid conditions. Diagnosis fixes the essential nature of the morbid condition, and thus not unfrequently indicates the requisite remedial measures, particularly as to surgical operations, manipulative procedures, and mechanical appliances; etiology supplies the knowledge of causes, which, if they be still in operation, must be removed; and prognosis determines the remaining indications of treatment.

A considerable portion of surgical treatment yet remains empirical; but it is now generally felt and acknowledged to be proportionately aimless, and as often therefore unsuccessful. Such treatment of injury or disease is like trying to hit a mark blindfolded. It can, indeed, only be regarded as a temporary resource, accepted by the Practitioner under the pressure of his natural anxiety to relieve human suffering in any possible way, but as often little better than nothing until enlightened by Pathology.

As thus directed, however, Treatment acquires three primary Indica-

tions of the highest importance. In proportion as the natural course of any morbid condition is towards an unfavourable issue, the Surgeon thence discovers the *earliest occasion* for interference, and the unfavourable conditions to be removed; while, in proportion as the Natural Course is towards recovery, it indicates the *least amount* as well as the *kind* of surgical assistance requisite, from time to time, to conduct the case to this happy issue. These three Indications of Treatment may be recognised more especially in respect to the general forms of Injury and Disease.

Treatment in accordance with the natural course of morbid conditions towards *recovery*, is evidently responsive to the requirements of a self-restorative or reparative power, which is inborn and inherent in the living body. Hence, I have long since designated such remedial treatment, "Conservative," whether in Surgery or Medicine, as denoting its preservative power, the timeliness and moderation of its remedial assistance. ("Medical Times and Gazette," 1864-65.) The term "Conservative Surgery," as originally understood, when introduced by Sir W. Fergusson in 1852 ("Medical Times and Gazette"), was restricted to operations for the preservation of some part of the body, which would otherwise have been inconsiderately and unnecessarily sacrificed. The performance of some operation of removal having become necessary, in consequence of an incurably diseased or injured state of a part; a lesser and limited operation, the extirpation of that part alone, may then be sufficient, instead of an operation involving also any portion of the sound organism. Of two, or more, practicable operations of removal, this consideration of anatomical preservation, may thus guide the Surgeon's choice. For example, excision of an incurable diseased joint, may be performed, instead of amputation of the limb. Thus, observes Sir W. Fergusson, a compromise may be made, whereby the original constitution and frame, as from the Maker's hand, may be kept, as nearly as possible, in its normal condition.

*Pathology in Surgical Operations.*—In the *design* and *performance* of Surgical Operations, the Guidance of Pathology, supplements and completes that of purely healthy Anatomy; this conjunction giving rise to what I have designated "Pathological Operative Surgery." (Ibid., 1865.)

The contrast between the Continental and the English Schools of Surgery, mainly turns on this more intimate incorporation of Pathology with Operative Surgery. Thus, in France, we find that it was advocated: by Sabatier (1832), Lisfranc (1845), Vidal (de Cassis) (1846), Sédillot (1853), Malgaigne (1861), Chassaignac (1861), Velpeau, and Nélaton. In Germany, the same position is urged by Chelius, Lühart, Dieffenbach, and Langenbeck. In Italy, by Scarpa (1809). America also has responded to this spirit of progress, as testified by Mott, Physick, and Gross. In this country, its influence has been more slowly felt. For, although in Scotland, so long since as 1801, John Bell overthrew the Anatomy of Surgery, as *then* taught in the schools, his denunciation was as "the voice of one crying in the wilderness;" and in England the purely Anatomical Operative Surgery of his brother, Sir Charles Bell, long prevailed. Nearly fifty years afterwards (1846) Liston noticed the influence of Pathological Anatomy on the "Abridgment" of Operative Surgery; by Sir William Fergusson, its occasional applicability in surgical operations was acknowledged in the third edition of his *Practical Surgery* (1852); and Skey recognised it in like manner in the second edition of his *Operative Surgery* (1858). In March, 1864, I brought prominently forward

in my "Principles of Surgery," the Guidance of Pathology in Surgical Operations, as a general Principle; positively true, in the great majority of operations, where the seats of operation and of disease or injury are identical; negatively true, in other operations, where the object is to operate clear of the disease and amid healthy tissues. I followed up this position at the dates already referred to; and more recently, Mr. Hancock endorsed the principle, as regards Surgical Operations on the foot, in his Lectures at the Royal College of Surgeons, 1866. Having exposed at some length "the very grave error," with reference to diseases of the foot, of "reducing conservative to mere anatomical Surgery;" he observes—"Experience has proved that we may do much more good by regulating our operative proceedings by the amount and character of the mischief; and hence I would venture, as suggested by Mr. Gant, to designate the Surgery of the foot, 'Pathological Surgery of the foot,' as being more comprehensive, as imposing this law upon us more strongly than does the term 'Conservative Surgery,' and, at the same time, implying the regulations which should govern us in our operative procedures."

Having thus traced the development of Modern Operative Surgery, it will be most advantageous in this introductory portion of the work, to show how Surgical Anatomy, properly so called, is modified throughout by constant association with pathological conditions, in the performance of any operation. Such an association will tend to correct the *purely* Anatomical impressions of the Student, and to safely guide the operating Surgeon.

It is only under the circumstances of disease or injury and life combined, in other words, Pathology, in conjunction with Anatomy, that the operating surgeon interferes. He is never called upon to touch the body in its healthy anatomical conditions. True, certain Operations are apparent exceptions to this otherwise unexceptional law. It may be, as I have said, that the seats of operation and of disease or injury are not identical; that our operation is somewhat removed from the diseased or injured locality. Such are amputations, and the ligature of arteries for aneurism. But even under these circumstances, pathological anatomy can alone determine whether or not we operate clear of the disease and amid healthy tissues;—whether, for example, the bone and soft parts left after amputation are healthy, and whether we cast our ligature around a healthy portion of artery. This *negative* application of pathological anatomy is obviously of the highest importance in respect to the successful results of surgical operations.

On all other occasions, the physical properties and relations of parts disclosed during an operation are then so changed by disease as sometimes scarcely to admit of recognition; and thus it is that anatomy *plus* certain pathological alterations, or the *pathologico*-anatomical conditions of the body, are those with which the operating surgeon is concerned.

Guided by this *à priori* principle, we can predicate those pathological conditions which from their nature must chiefly influence the performance of surgical operations;—alterations of certain physical properties, more especially of colour, consistence, and elasticity; also modifications of shape and size, with those affecting the situation, position, and relation of parts; such peculiarities altogether change the scene with which the mere anatomist is familiar.

Nor are these the only circumstances that overshadow the appearances to which he is accustomed. Whoever has observed the arm of a dead sub-

ject as it lay extended over the side of a dissecting-table, must have been struck with the well-marked bicipital depression, especially visible on a thin subject. If injected, the brachial artery can almost be distinguished as a prominent line throughout its course. Apparently, a single incision would bring one down upon the vessel, and so it does. The skin, gluey and adhesive, hangs upon the knife; nor does the incision gape; the artery is soon exposed, not being overlaid by the contracted biceps, and only, perhaps, obscured by the turgid vein on its inner side. Contrast all this with the same proceeding during *life*. We observe no such well-defined groove to guide our incision; the skin yields before the knife with a crimp and elastic resistance; the wound gapes; the swollen and vibratile belly of the biceps muscle, especially if amply developed, overlays the artery, while the vein, perhaps not so turgid, immediately conceals it. More or less hæmorrhage will also further obscure the vessel, which can only be recognised by its beautiful fawn-colour and its pulsating under the finger. I have purposely excluded the brachial plexus of nerves from this sketch, in order more clearly to contrast the *dead* with the *living*.

This illustration will apply, *mutatis mutandis*, to operations for the ligature of other arteries; and the experience of every practical Surgeon will supply him with the more extended application of the same principle during all other surgical operations.

We must, therefore, acknowledge also the guidance of *living* (not merely functional) conditions during the performance of surgical operations. The condition of life modifies certain physical appearances, and chiefly those affected by *pathological* anatomy. Thus, the colour, consistence, elasticity, and even the size and shape of the various parts of the body, their situation, position, and relation to contiguous parts, are presented to the Surgeon, when modified by the twofold conditions of *Disease* and *Life* combined.

These together may be termed Pathology, and not Pathological Anatomy, which represents only *dead* structural disease. PATHOLOGY,—conjoined with Anatomy,—is, therefore, our guide during surgical operations. In proportion as we are familiar with pathological conditions, by so much are we enabled to foresee, and to provide for, the peculiar appearances and conditions which the knife discloses, and to recognise them as they are successively presented in surgical operations.

Guided by this anticipatory knowledge, our operations are no longer discoveries made by dissection, but *planned* and *methodical* proceedings, conducted on known principles—in fact, an ART, based on the science of Anatomy supplemented by Pathology.

When a pupil of the late Robert Liston, I frequently witnessed, and for many years observed with care, the operations of that illustrious surgeon; and I venture to affirm, that if one circumstance more particularly contributed to the ease and elegance of his operations, it was the *suitable* (artistic) *method* on which he planned and conducted them. If I might use the expression, there was a kind of *slow-quickness* about all he did,—the former quality indicating the method he pursued, the latter resulting from its sufficiency and skilful application.

The twofold Principle I have advanced might be further elucidated by tracing the *combined* influence of disease and life on the scenes of the chief Operations of Surgery. A series of such illustrations are given in my work on “Principles,” and Pathology, with Anatomy, will be found

to govern the design and guide the performance of these and other operations generally, as described in the course of this work.

Without the knowledge of Anatomy, attired in the garb of disease and life, neither safety nor success can be attained in the planning and performance of Surgical operations. "The operator,—I would say without this knowledge, is seen agitated, miserable, trembling, hesitating in the midst of difficulties, turning round to his friends for that support which should come from within, feeling in the wound for things which he does not understand; holding consultations amid the cries of the patient (before the days of chloroform), or even retiring to consult about his case, while he lies bleeding, in great pain and awful expectation."

But, no less important in Operative Surgery, is the knowledge, chiefly Pathological, to which I would next direct attention, as mainly determining the *success* of operations.

CONDITIONS FAVOURABLE AND UNFAVOURABLE FOR OPERATION.—The selection of cases fitted for Operation should always most seriously engage the Surgeon's consideration.

The Conditions Unfavourable for any Surgical procedure being known, all other conditions may be presumed to be favourable.

*Unfavourable* conditions comprise: (1) certain states of the Patient's Health, constitutional, and local in regard to the seat of disease or injury; (2) the Hygienic conditions by which he is surrounded.

*Constitutional* conditions unfavourable for Operation, relate both to the mind and body.

Persons who are naturally of an irritable and anxious, or of a desponding, *mind*, cannot sustain a surgical operation so well as those of a tranquil and cheerful disposition. This rule holds good also in the case of persons who, from temporary circumstances, may be mentally affected in like manner. And especially unfavourable, is any despondency respecting the issue of the operation itself. This adverse influence affecting the Patient's bodily health, before and after the operation, will be alone sufficient to undermine the result of any skill on the part of the Surgeon. On the other hand, the sustaining influence of hope is well exhibited by the fatal effect produced when it is suddenly withdrawn. Sir A. Cooper tells the story in his Lectures of a poor countryman in Guy's Hospital, who, lying in bed previous to a capital operation, was asked by a student what part of the country he came from; Cornwall he replied. Then said his interrogator,—you will never see Cornwall again. Nor did he; the man never rallied.

An instance of such heartless or thoughtless indiscretion, suggests the kind of address and tact, animated by honest sympathy, with which the true Surgeon will manage his patient's mental disposition, ever fairly supporting hope as the well-spring of life.

Conditions of *bodily* health, of a constitutional character, unfavourable for Operation, are numerous. They relate to all the organs of the body, and vary in importance according to the physiological agency of the organs in maintaining life. Thus, the nervous system, the heart, lungs, digestive organs, and excretory organs, especially the kidneys and skin, have severally to be considered, and from a twofold point of view. Firstly, organic conditions must be considered, as affecting the general health, and thence the life, of the individual, when subjected to any particular surgical operation; and, secondly, they should be regarded in relation to reparation, or the reserve-power of nutrition requisite

after any operation of magnitude, and which necessarily also entails an ordeal of some duration for the system to undergo, before the health can possibly be re-established.

The state of the *nervous system* is a primary consideration. When itself naturally irritable, or when in an irritable state for the time being, this condition is peculiarly unfavourable for surgical operation. It seems to be associated with a weak circulation, and the patient is apt to sink soon after any severe surgical procedure. But the judicious administration of opium with wine, brandy, or other stimulants, will often succeed in preparing the patient for operation, and carry him or her through the critical period subsequently. Chloroform, besides preventing pain, has a specially beneficial influence in irritable nervous persons, subjected to operation for surgical disease, or when the circulation is depressed by the shock of injury.

Certain *blood-diseases* prohibit any surgical operation, otherwise than one of immediate necessity for the preservation of life. Thus, any operation of choice should be postponed when the patient is labouring under erysipelas or pyæmia. Other diseases have not a fatal tendency, yet their existence is adverse to the successful result of an operation. Such are scrofula, and the contamination of the system by malignant disease. In the latter case, an operation will be almost surely followed by a return of the disease, *in situ*, or its development in some distant part.

*Heart-disease*, and particularly fatty degeneration of this organ, should make the Surgeon consider the necessity or the advantage of any operation attended with much loss of blood or shock to the nervous system. Consequently, when the pulse is habitually feeble, irregular, and perhaps slow, the patient breathless on slight exertion, and marked with the arcus senilis; these symptoms co-existing, almost surely indicate fatty degeneration of the heart, and should warn the Surgeon that he has a bad subject to deal with.

*Lung-disease* does not seem to have so important a relation to Surgical Operations. This may, perhaps, be explained by the fact that after any severe operation, the patient being confined to bed, there is no special demand on the function of the lungs as the organs of respiration. As double organs also, one may be more or less diseased and incapacitated, and the other fulfil a double or compensatory function, and especially in the case of old-standing disease. Phthisis is an exceptionally unfavourable condition, and particularly if this disease be in an active state or in an advanced stage. The operation for fistula in ano, a disease often co-existing, should not be performed under these circumstances.

The *Digestive-organs* play a most important part with regard to the result of surgical operations, and disorders or derangements of these organs demand the most careful consideration. Obviously this is due to the necessity arising after any operation of magnitude, for an extra supply of nutritive material to meet the demands of the reparative process, a supply which implies an active state of the digestive organs incompatible with any kind of indigestion. Irritable dyspepsia, and hepatic derangement, terms not very definite, but sufficiently familiar in practice, represent the conditions which are most adverse to surgical procedures.

The *kidneys* and *skin*, as excretory organs, have a grand relation to surgical operations by purifying the blood of noxious matter, the retention of which would inevitably spoil the material requisite for reparation.

Disease of the kidneys, in the various forms of degeneration, accompanied with albuminous urine, and the retention of urea in the blood, constitutes the most unpropitious condition under which a patient can be subjected to operation. The wound is apt to undergo diffuse inflammation and sloughing, while the patient sinks rapidly from the exhaustion of blood-poisoning. This seems to arise from the local products of inflammation, thus induced, becoming absorbed, and accumulating in the blood, soon overwhelm the system beyond the endurance of life, when already oppressed by the uræmic poisoning. In this condition also, both kidneys are diseased, so that there is no chance of any relief by one organ compensating for the functional deficiency of the other, as in the case, sometimes, of the lungs.

The state of the skin must also be taken into consideration before undertaking any operation. A cool, moist, soft, perspiring skin is no less conducive to success, than a free secretion of healthy urine. Chronic diseases of the skin, such as lepra or psoriasis, involving a large extent of the cutaneous surface, had better be treated before proceeding to any surgical operation which can be postponed.

*Pregnancy* does not prohibit any surgical operation, excepting in so far as this state may thereby be itself affected. In the case of a lady advanced in pregnancy, I have removed a large slough from the abdominal wall by incision, without disturbing the course of pregnancy; but, on another occasion, in the same person, the removal of necrosed bone from the scapula, under the influence of chloroform, was followed by a miscarriage the next day.

*Obesity* is said to be, in itself, a condition very unfavourable for operation, owing to the feeble circulation in such subjects. *Old age* naturally renders an individual less able to sustain the shock of an operation, and the loss of blood; subsequently also there is less power to pull through to recovery.

*Idiosyncrasy*, or some unknown constitutional condition peculiar to the individual, may prove singularly prejudicial to the success of even a trifling operation. Thus, in one case, after removing a small fatty tumour from the abdominal wall, on the following day the adjoining integument presented a sphacelated black patch, with an abundant, thin suppurative discharge from between the lips of the incision.

*Local* conditions unfavourable for operation relate to any diseased state of the part itself, which will tend to produce an unsuccessful result. Thus, acute inflammation of a joint, for example, would be adverse to excision; and a sloughing condition of the parts involved in the flaps of an amputation, would defeat the purpose of this operation. Cancer, or disease of a malignant nature, should never be removed, unless the whole disease can be freely extirpated. Any portion beyond the reach of operation will necessarily cause a return of the disease, *in situ*; an important consideration, in addition to the question of probability as to the development of cancer in some distant part.

*Hygienic Conditions.*—Besides the state of health, constitutional and local, by which a patient may be in an unfavourable condition for operation; the hygienic circumstances in which he is placed, both before and afterwards, will much affect the probability of success. Adverse hygienic conditions comprise chiefly: Defective Diet, in quality, quantity, or in both respects; overcrowding of the sick and wounded, especially those having open and suppurating wounds, or Deficient Ventilation; Exposure

to Contagious or Infectious matter, by dressings or inhalation, as in the propagation of Hospital gangrene and erysipelas. The *minimum space* allotted to each patient in the Surgical Wards of an Hospital should be 1500 cubic feet of air to each person. And this quantity must be accompanied with change of air also, by proper ventilation.

*Preparation of Patient for Operation.*—It is scarcely necessary to observe that, on the ground of personal liberty of the subject, and legal liability of the surgeon, the consent of the patient, and of his or her immediate relatives, should first be obtained before proceeding to any surgical operation. But this rule will as necessarily admit of exceptions, according to the mental capacity, or the age of the patient; the more or less urgent nature of the case proposed for operation.

If the patient be sensible, of sound mind, and mature age; and he resolutely and persistently refuse to allow an operation of urgency to be performed; and if, moreover, his determination be backed by that of an immediate relative, as his wife; the Surgeon will have no alternative but to give up the responsibility of the case. Thus, I have seen a man die from strangulated hernia, in spite of the earnest and repeated remonstrances of the Surgeon to him, and his wife, as the strangulation proceeded to a fatal termination. On the other hand, if the patient be insensible, or imbecile, or in the case of a child or infant, and in the absence of immediate relatives or parents, the operation being an urgent one, the Surgeon will be free to act according to his own judgment.

The preparation of the patient, mentally and bodily, will consist in inspiring him with cheerful hope, and in bringing his bodily health to a quiescent condition, especially observing that the actions of the digestive organs, and of the skin and kidneys, are healthy, when time can be allowed for any such preparation. This tranquil, even state of mind and body, is that best fitted for operation. But, when no time can be permitted for any constitutional preparation, as after most severe injuries, the patient must be at once submitted to operation.

*Arrangements for Operation.*—The arrangements requisite for the efficient and convenient performance of surgical operations, relate to the Room, the Operating-table, Instruments, with other Appliances, and Assistants.

The *Room*, of convenient size, should admit a good light, an over-head or skylight being very desirable for most operations; it must be adequately warmed in cold weather, or for the performance of operations wherein the abdomen is opened and the viscera exposed, as in operating for strangulated hernia and in ovariectomy; but there should also be the means of free ventilation or change of air about the patient, when under the influence of chloroform. Besides the requisites of light, temperature, and air, an ample supply of water, warm and cold, must be at hand.

The *Operating-table* must be strong, and firm-standing (not moving on castors), of convenient height, and width only of the body, covered with blankets overlaid with india-rubber sheeting, and provided with pillows. The tables constructed for operation, as used in Hospitals, are fitted with a mechanism for raising the head and shoulders to any requisite height; and flaps are provided for leaving the legs unsupported, as for amputation, or when the nates are placed so as to rest over the end of the table, as for lithotomy, and other perineal operations. A low, firm stool will be a requisite accompaniment for these operations, to seat the operator in cutting for stone, or an assistant in holding the leg for amputation.

An Operating-chair, instead of a table, is necessary for cases wherein the patient is seated; as in operations about the face, the extraction of nasal polypi, for cleft-palate, or the removal of either jaw; also, for other operations, as amputation at the shoulder-joint, and tapping the abdomen. The chair itself, firm-standing, and high-backed to support the head, much resembles a dentist's chair. These arrangements respecting the room and table should be seen to by the Surgeon himself, when not regularly provided as in a Hospital; but the remaining provisions, as to instruments and assistants, must always be personally superintended.

The *Instruments* necessary should be well selected with regard to the nature and possible complications of the operation; and for convenience, they should be arranged on a small table or tray, in the order in which they are wanted, and placed near the Surgeon, so that he can help himself to any instrument he may require, or have it handed to him immediately by an instrument-assistant. The collection of instruments, however few, had better be covered with a towel, to conceal them from the eye of the patient when brought into the room. Sponges, of various sizes, clean and compressible, with lint and plaster, will always be provided by any well-trained nurse; but here again, the Surgeon had better see that these appliances are at hand. Any splint or other accessory requisite for application after operation, and previously prepared by the nurse or an assistant, should also be inspected. A tray containing saw-dust or sand may be placed on the floor so as to catch the blood; but this has a repulsive appearance, and it is more agreeably substituted by a piece of maroon-coloured oil-cloth under the table. The operator may be conveniently dressed, in an easy-fitting, long cut, alpaca coat, or dressing-gown.

The *Assistants* should be in number sufficient, but not superfluous, and each should have an allotted duty to perform, orderly and silently. Thus, for a capital operation, as amputation, joint-excision, or lithotomy, four, or not less than three assistants, will be required; one, specially to administer chloroform; then, in the first-named operation, another to command the main artery; a third to hold the limb in position; and a fourth to take charge of the flaps, and ligature the vessels as they are seized by the Surgeon. A fifth assistant might hand the instruments; but they are often taken up most readily by the Surgeon from the table near to him.

**ANÆSTHETICS.**—The greatest gift of God to man, through Natural Science, is, perhaps, the discovery of means for the prevention or the abolition of bodily pain. This exemption approaches the realization of that blissful hereafter, one of the Divine promises of which is, that then "there shall be no more pain."

Glimpses of the truth as now made known have appeared in various ages; but it was not until the year 1800 that Sir Humphry Davy, having himself experienced relief from pain while breathing nitrous oxide gas, suggested the possibility of employing the influence of this agent for the same purpose in surgical practice. After the lapse of nearly half a century, in 1844, the same idea occurred to Dr. Horace Wells, a dentist in Hartford, America, who underwent the extraction of a tooth without pain after inhaling the gas, and he administered it with the same effect to several of his patients; but, finding the practice uncertain, he soon abandoned it. About the same time, Dr. W. T. G. Morton of Boston, in

America, who had previously been a partner with Wells, sought of his own accord, without it would appear receiving any suggestion from him, to discover an efficient anæsthetic; and having experimented upon himself and the lower animals, he extracted a tooth painlessly from a patient, under the influence of sulphuric ether by inhalation; this event taking place on the 30th of September, 1846. He then publicly exhibited the efficacy of this agent at the Massachusetts General Hospital; and thenceforward anæsthesia in surgery became an established blessing to mankind.

It was not long ere this invaluable discovery was recognised, and followed up by farther investigation in this country; which resulted in the introduction of *chloroform*, and its employment instead of sulphuric ether. The latter agent is still extensively used as an anæsthetic in America; but in Europe, chloroform is now generally preferred to it. Disguised under the name "chloric ether," in which it exists diluted with spirit of wine, this agent was employed by Dr. Morton in his first experiment upon himself; and it is a fact, not perhaps generally known, that it was also used in the same form, in preference to sulphuric ether, by Mr. Lawrence, at St. Bartholomew's Hospital, in the summer of 1847. Mr. Paget confirmed this fact by information communicated to Mr. Lister; to whose article on anæsthetics, in *Holmes's Surgery*, I am indebted for the particulars of the foregoing historical sketch, and for much which follows on this subject.

It was in the autumn of 1847 that Dr. Simpson, who was engaged in a series of experiments with various narcotic vapours, employed for the first time the active principle of chloric ether, at the suggestion of Mr. Waldie, of the Apothecaries' Hall of Liverpool; and finding that pure chloroform had certain advantages over sulphuric ether, he zealously recommended it to the Profession, and it has since been generally used. The advantages alluded to in favour of chloroform are, that it is a more potent anæsthetic, its inhalation causes less bronchial irritation, its odour is more agreeable, it is less volatile, thereby rendering its administration more easy; and lastly, the vapour of chloroform not being inflammable like that of ether, it is fitted for operations by artificial light.

**CHLOROFORM.**—This anæsthetic agent will be briefly considered in regard to:—its physiological action; the phenomena produced by inhalation; the question of its contra-indication in certain diseased conditions of the system; the method of administration; death from chloroform; and the treatment of an over-dose.

*Physiological Action.*—The action of chloroform on the functions of the nervous system is such as to render it exactly suitable for the purposes of surgical practice. Chloroform is a narcotic, and like most medicinal agents of this class, it produces temporary excitement, followed by suspension of the functions of the nervous centres; but it affects them not simultaneously, but in a certain order. The *brain* is the first to evince loss of power, in the failure of sensation, including consciousness, and voluntary motion; the *spinal cord*, or rather the whole cerebro-spinal axis, secondly, soon loses the reflex function of involuntary excito-motion, so far as regards the voluntary muscles, which lie perfectly relaxed and passive. This combined state of insensibility to pain, paralysis of muscular action, voluntary, and involuntary with regard to the voluntary muscles, presents a condition most favourable for the performance of surgical operations. On the other hand, the *involuntary* action of the muscles engaged in respiration remains, and the action of the heart, as dependent

on the ganglia of the sympathetic nerve, continues. Thus then, while the whole physiological condition of the nervo-muscular system suits the convenience of the Surgeon, and the patient is rendered insensible to pain; those dependent functional actions are retained which are essential to life.

Certain other important advantages attend the inactivity of the cerebro-spinal centre. The shock of injury, which would be increased by the additional violence of surgical operation, is diminished under the influence of chloroform; thence, the contractile power of the heart, as affected by the action of the brain and spinal cord upon the cardiac ganglia through the medium of the pneumogastric and sympathetic nerves, is unreduced by such violence, thus averting the tendency to *cardiac syncope* and death during operation; and lastly, in the absence of faintness, the vessels bleed freely, and by at once declaring those which require ligature, the liability of *secondary hæmorrhage* is prevented. Moreover, the mental tranquillity secured before operation by the prospect of immunity from suffering, is a condition highly favourable to recovery afterwards.

*Phænomena or Symptoms* produced by the action of chloroform.—After inhalation for a time, varying considerably in different individuals, but generally of longer duration in adults who have been accustomed to the free use of narcotics, and shortest in children, symptoms of excitement are manifested by various ejaculations, and by muscular rigidity and movements requiring some restraint; but this state is soon and suddenly succeeded by complete relaxation and insensibility, accompanied with deep heavy respiration. Or, without any previous stage of excitement, the patient may at once pass into a state of tranquil sleep. The suspension of reflex action is denoted by the absence of unconscious winking when the eye-ball is touched with the tip of the finger, as a stimulus; a state commonly regarded as insensibility of the conjunctiva. The heart's action, and pulse, at first quickened and more forcible than natural, subsides under the influence of chloroform, and becomes slow and feeble or scarcely perceptible. The respiration also becomes feeble and imperfect, and the blood proportionately venous; a state approaching or bordering on asphyxia. Snoring or stertorous breathing is soon induced, passing into complete obstruction to the entrance of air into the chest, although the respiratory movements of the thoracic walls still continue. Occasionally, without any premonitory stertor, the breathing becomes more or less suddenly obstructed, and a livid turgescence overspreads the face. Death is imminent where inhalation is carried to this degree as regards either the circulation or respiration; and whether as the result of administering a highly concentrated vapour, or of long continued inhalation.

There are instances occasionally of persons who, from some peculiar idiosyncrasy of constitution, are incapable of being affected by chloroform; they are proof against its anæsthetic influence. Thus, I have known four ounces of chloroform administered to a lady, by inhalation, without producing the slightest effect.

*Contra-indications* to the employment of chloroform.—Certain constitutional conditions and organic diseases, are said to prohibit the use of chloroform, or to require extreme caution in its administration. The influence of *shock* has already been adverted to, in speaking of the physiological action of chloroform. Pain is not a stimulant but a depres-

sant, and therefore the performance of an operation during the continuance of shock, and without chloroform, would increase the collapse; and, moreover, as already explained, the influence of this agent protects the action of the heart from the tendency to cardiac syncope, resulting from the pain incident to an operation. Hence, operations may be safely performed, under the influence of chloroform, during the shock of injury; thus overturning the old rule of postponing operation, amputation for example, until the patient has recovered from the state of collapse. The system may be at once relieved from the injurious presence of a mangled limb, or life preserved where it would be hopeless to wait for returning consciousness. But, during shock, it is unnecessary to give chloroform to its full extent; but only so far as to benumb sensation in the incisions or painful part of the operation.

*Epileptic* persons may be subjected to the influence of chloroform-inhalation, administered cautiously, however, considering their liability to suffer from congestion of the brain.

*Hysterical* persons are said to be subject to laryngeal spasm, during inhalation.

*Disease of the Heart* does not absolutely contra-indicate the administration of chloroform, but only that it be given with extreme caution; watching the pulse especially, and the breathing. In *fatty degeneration* of the heart, the sedative influence of chloroform is liable to suddenly arrest the action of this organ with instant death. In *valvular* disease there is less danger.

*Disease of the Lungs* is not specially obnoxious to inhalation. In *phthisis*, not far advanced, no difficulty arises; but with bronchial irritation, troublesome cough is apt to be produced.

*Disease of the Kidneys*, resulting in degeneration of these organs, and the retention of urea in the blood, is a condition decidedly unfavourable for the administration of chloroform. Congestion of the brain being superadded to the uræmic-poisoning, may induce epileptic convulsions, with lividity of the face, stertorous breathing, and coma.

All *Surgical Operations* allow of the employment of chloroform, excepting a few in which the assistance of the patient is required, and in operations attended with copious hæmorrhage into the mouth. In some cases, however, pain may be prevented to a great extent, by giving chloroform during the earlier or more superficial parts of the operation.

*Age* is no objection to the employment of chloroform; infants and octogenarians taking it with safety.

*Administration of Chloroform.*—Prior to giving chloroform, the patient should be directed to omit taking food for four or five hours, as the presence of any food in the stomach is apt to cause troublesome vomiting during inhalation. The patient lying recumbent with the head and shoulders just comfortably elevated on a pillow, he should not be allowed to raise himself in any struggling excitement, or be raised, into the sitting posture whilst under the influence of chloroform, lest cardiac syncope take place. Any tight band around the neck or waist should be loosened, the breast had better be exposed, and care should be observed not to subject the thorax or the abdomen especially, to any compression, as the respiration becomes principally diaphragmatic.

Chloroform may be administered simply on lint or a handkerchief, or by means of an inhaler of some kind. The former mode is in general use, it being equally safe, provided only two precautions be observed;

the chloroform must not be given too suddenly, or the vapour breathed in too concentrated a state or without a free admixture of air.

The mode of administration is simply this: a piece of lint or a handkerchief folded two or three doubles, and about the size of the hand, is sprinkled with a drachm or two of chloroform; it is then held near the nostrils, but so as to admit a free admixture of air with the first few inhalations; after the lapse of about a minute, a towel may be placed over the face of the patient and the hand of the chloroformist to enclose the vapour, still observing to admit the air freely under one corner or one-half of the towel. This is continued, interrupted perhaps by the temporary excitement and struggles of the patient, until the arm falls involuntarily and relaxed when raised, and the eyelid ceases to move when the conjunctiva is touched with the finger. During the course of inhalation, the chloroformist should have his other hand on the pulse, carefully feeling its force and frequency, while at the same time he unceasingly watches the breathing. If at any moment, earlier or later, during inhalation, the pulse sinks to a feeble, slow beat; or if the breathing becomes strongly stertorous; immediately discontinue the administration of chloroform; and for the relief of the respiration, at once seize the tip of the tongue, with forceps or the fingers, and draw it firmly forwards out of the mouth, until the tendency to obstruction has subsided. The breathing returns with perfect freedom, and the overshadowing lividity of the face disappears. Chloroform can then be cautiously reapplied, if necessary.

*Inhalers* of various kinds have been devised for the purpose of regulating the proportion of chloroform and the admixture of air. Snow's inhaler, or Clover's chloroform apparatus, may be employed; and the latter is spoken of very highly by those who have used it, as being most efficient. But simplicity with efficiency is always a great recommendation, and thus the administration of chloroform by means of a piece of lint or a handkerchief can be accomplished at once, when any form of inhaler may not be at hand and would have perhaps to be fetched from a distance of some miles off. Even in Hospitals, inhalers are not commonly employed.

In point of safety, the two methods of chloroform-administration are equally available, provided only that a free admixture of air be attended to. I have seen chloroform given in some thousands of cases without an inhaler, during upwards of twenty years, both in Hospital and private practice without a single death, or even an approach to a fatal termination, when the requisite precaution for safety has been observed.

*Death from Chloroform.*—During inhalation, death may occur in three different ways: by asphyxia, by cardiac syncope, or by coma; through failure of the respiration from insufficient aëration, or by laryngeal obstruction; failure of the heart's action; or congestion of the brain.

*Asphyxia* is indicated by the ordinary symptoms: lividity and turgescence of the face, violent respiratory efforts, and cessation of the pulse, and of the heart's action. These symptoms may arise simply from deprivation of air resulting in a highly venous state of the blood; but stertorous or snoring breathing is superadded, when the asphyxia arises from laryngeal obstruction. The cause of this obstruction is generally attributed to a "falling back of the tongue," thus mechanically obstructing the entrance of air through the larynx. But Mr. Lister has specially investigated the question, and he finds that the obstruction arises from an

approximation of the apices of the arytaenoid cartilages towards, or to, the base of the epiglottis; the stertorous breathing resulting from the vibration of the corresponding portions of mucous membrane, the posterior parts of the arytaeno-epiglottidean folds. Traction of the tongue firmly forwards abolishes the obstruction and stertor, not by any mechanical action on this part of the larynx, for the base of the tongue and hyoid bone remain unmoved in position. It would appear that such traction operates by reflex action through the medium of the nervous system, but whether by inducing or relaxing muscular contraction in the larynx, is uncertain.

*Cardiac Syncope* always occurs suddenly. The patient, after a few inspirations, suddenly becomes pale and faint, the pulse beating almost imperceptibly for a few moments, and then ceasing, although the respiration may continue; death taking place by paralysis of the heart. This organ may itself be healthy, but more frequently it will be found to have undergone fatty degeneration.

*Coma* presents the same appearances as asphyxia, but without failure of the heart's action. The face becomes livid, the breathing stertorous, and the body convulsed; the heart continuing to beat up to the last, as death results from congestion of the brain. This mode of death occurs mostly in epileptics, and in persons affected with uræmic blood-poisoning from old-standing renal disease.

These three modes of death are referable generally to the incautious administration of chloroform; whether as regards an excess of chloroform in proportion to the admixture of air, or the prolonged inhalation of this anæsthetic agent.

*Persistent Sickness* is another occasional cause of death; but it occurs after the administration of chloroform, and seems to be a consequence of some idiosyncrasy of the individual. I have only known one case, death having occurred from the exhaustion of continued sickness for four days after amputation of the thigh for encephaloid cancer of the knee-joint, in the person of an otherwise apparently healthy young woman. In another case, after excision of the knee for scrofulous disease, in the person of a young woman, sickness set in and continued for a week; but it was subdued by the hypodermic injection of morphia, while life was sustained by nutritive enemata.

*Treatment of an Over-dose of Chloroform.*—The indication to be fulfilled will vary according as the symptoms, or apparent mode of death, arise from asphyxia, or from cardiac syncope; the object being to re-establish the respiration, or to stimulate and restore the heart's action and the circulation. But in either case, the following directions should be carried out immediately, and in combination:—

The administration of chloroform must at once be discontinued.

Firm traction of the tongue must be immediately had recourse to, this being effected by seizing the tip of the tongue with fingers or forceps and drawing it well forward out of the mouth.

Air must be allowed to circulate freely around the patient, by opening the nearest window and the withdrawal of bystanders.

The chest exposed and free of constriction, should be whipped or flagellated with a wet towel in order to stimulate reflex respiratory action.

This failing, artificial respiration should be resorted to; the best mode being compression with the hands just below the sternum, by a sort of

sharp concussive jerk, followed by relaxation for expansion of the thorax, while the tongue is still drawn out of the mouth.

Electricity may be employed as the last resource, by applying one pole of a galvanic battery over the spinous processes of the upper cervical vertebrae and the other to the præcordial region, so as to stimulate the respiratory and cardiac ganglia.

Friction of the extremities, and bottles or cans of hot water to the feet, may also be used, to promote the general circulation.

These means of resuscitation should be continued perseveringly while any sign of vitality remains, for it has happened that a patient apparently irrecoverably dead has thus at length been restored to life.

*Bichloride of Methylene* and *Chloral* are anæsthetic agents which have recently been added to those already noticed—nitrous oxide gas, sulphuric ether, and chloroform. For this addition we are indebted to the experimental researches of Dr. B. W. Richardson.

Bichloride of Methylene has, Dr. Richardson states, been administered at present (Oct. 1869) to between six and seven thousand persons with only one fatal termination. It occurred in a patient of Mr. Canton's, on whom he was about reluctantly to operate at Charing-Cross Hospital, for advanced malignant disease of the upper jaw. The patient, a man thirty-nine years of age, was previously exhausted, bodily and mentally, by great suffering of three months' duration, the apparent date of the disease; one nostril was closed by the tumour, thus obstructing respiration, and the patient was subjected to the influence of the bichloride in a sitting posture. One drachm and a half, in separate quantities, had been administered, when the man's head fell back, the pulse became feeble, and then ceased. There was no accompanying stertor nor lividity of countenance. The horizontal position, artificial respiration, and galvanism, failed to restore life.

Chloral is, by some observers, said to possess powerful anæsthetic properties; others deny that it is an hypnotic or anæsthetic, but regard it as a powerful excitant.

**LOCAL ANÆSTHESIA.**—The application of cold to a part of the body, in order to reduce the temperature of that part to a frost-bitten condition, is a mode of anæsthesia which may be advantageously employed in certain surgical operations. It is eligible in all superficial and limited operations, in regard both to their extent and the time requisite for their performance. Such are, the avulsion of a toe-nail, puncturing abscesses, slitting up fistulæ, and the excision of small tumours.

Freezing of the part operated on may be effected either by the application of a frigorific mixture, as introduced by Dr. J. Arnott, or by the ether-spray, devised by Dr. B. W. Richardson.

The frigorific mixture of pounded ice and salt is easily made, and answers admirably. This mixture is put into a muslin bag, and applied to the part, being raised in a minute or two to see whether the desired effect has taken place. The skin almost immediately loses its colour and becomes white, a change the more observable when previously reddened by inflammation; but this blanching of the skin is no sign of freezing having occurred; soon, however, a dead white, opaque spot appears, quickly spreading over the cutaneous surface, and then the part is frozen and anæsthesia produced. The integument cuts hard, like parchment, and the blood is singularly florid. Reaction speedily sets in, and the part recovers itself. No constitutional disturbance accompanies, or ensues

from, this freezing of a part of the body. I have seen or known only one case of any unfavourable consequence. The patient, a healthy, florid young woman, had sat and seen me remove one of her great toe-nails, looking at the operation with perfect indifference; but when reaction took place, she suddenly fainted, and again and again, until the syncope was alarming.

The *Ether-spray* is another means of freezing a part and inducing local anæsthesia; but in this method it is effected by evaporation of ether thrown upon the surface in the form of a fine spray from a little apparatus contrived by Dr. Richardson for the purpose. It offers a more ready method for the convenience of surgical practice, as it may always be kept at hand; whereas ice cannot always be obtained. Unfortunately, so far as my experience has gone, the apparatus, simple in itself, usually seems to be out of working order when wanted.

DANGERS ATTENDING, OR CONSEQUENT ON, SURGICAL OPERATION.—The perils pertaining to operation are principally as follows:—(1) Hæmorrhage, primary and secondary; (2) Shock; (3) Tetanus; (4) Inflammation; (5) Gangrene; (6) Erysipelas; (7) Pyæmia. Of these different contingencies, some are coincident with, others consequent on, the operation. They will all be fully considered in various chapters of this work.

DRESSING OF THE WOUND, AND CONSTITUTIONAL AFTER-TREATMENT.—The dressing of a wound made by surgical operation is the same as that of any incised wound; and the dressings will vary with the supervention of inflammation, and its consequences—Suppuration, Gangrene, and Ulceration. The Constitutional After-treatment must have reference to the various states of the system in the contingencies already alluded to; and to those resulting from inflammation—namely, Inflammatory Fever, Hectic, and Gangrenous-typhoid febrile disturbance. All these states also are considered in their appropriate chapters.

RESULTS OF OPERATION.—The object or purpose of any Surgical procedure should be viewed with regard both to its temporary and its permanent results. An operation may be successful from the one point of view, but not from the other.

The unsuccessful results of any Surgical procedure may, perhaps, be reduced to three general heads:—(1) A return of the original condition for which the operation was performed; (2) the substitution of some new condition, not better, or worse, than the first; (3) the inducement of disease in some distant part of the body. Of the two first modes of unsuccessful results, such instances may be cited, as, after amputation of a limb, the return of gangrene in the stump; after excision of a joint, the substitution of a useless limb. The third mode of unsuccessful result is illustrated, after ligature of an artery for aneurism, by the development of aneurism in another part; or after the excision of cancer-growth, the development of internal cancer.

# PART I.

## GENERAL PATHOLOGY AND SURGERY.

---

### DISEASES OF NUTRITION.

---

#### CHAPTER I.

##### INFLAMMATION.

INFLAMMATION may be defined to be a modification of Nutrition; consisting, essentially, in an increased textural productiveness and destruction of texture, and *acceleration*, therefore, of the nutritive process; resulting in an accumulation of mixed, organized matter,—partly, of products, having an imperfect structural homology or resemblance to healthy conditions of texture or textural elements, and partly, of *débris* or waste of the textures involved. In connexion with this process of accelerated and imperfect nutrition, the local circulation of blood, and the containing vessels, undergo certain changes; an increased flow or *determination* of arterial blood to, and in, the capillary vessels, at the seat of inflammation, stagnation and accumulation or *congestion* of blood in the capillaries of the inflamed part, the veins transmitting the increased current of blood through collateral capillaries—with enlargement of all the vessels concerned,—vascular changes which are accompanied with an effusion or exudation of organizable plasma or liquor sanguinis. The condition of the local circulation in the capillaries is known as the *stasis* of the circulation in an inflamed part.

This complex process has the most comprehensive significance, both pathological and practical; having relation to all Injuries, Diseases, and Surgical Operations. Hence, a due knowledge of Inflammation and its consequences, is of primary importance in the study of Surgery.

The pathology of Inflammation is most appropriately introduced by a brief consideration of the physiology of healthy Nutrition,—in the maintenance of the structural integrity of the body, and the modifications of this process in growth and development.

NUTRITION is that process, wherein the blood or its constituents as nutritive material—liquor sanguinis, plasma or blastema, is converted into the various textures and organs of the body; thereby restoring or repairing the loss or waste of their structure, which continually accompanies the exercise of their respective functions. The changes which the nutritive material undergoes are of two kinds:—chemical, in respect to its composition, plastic or formative, as productive of structure; analogous but opposite changes taking place in the course of decomposition and destruction of the textures.

In any diseased modification of Nutrition, as Inflammation, the process

is essentially the same in kind, differing only in degree. Hence, the products or structural results, and their appearances in course of destruction, are the same, differing only in character. Parallel, but apparently less definite, modifications of chemical composition, may be inferred.

The process of Nutrition may be traced, to some extent, in certain tissues, which, being situated on the surface of the body, are open to observation. Epidermic tissues, namely, scarf-skin or cuticle, nails and hairs, are thus patent. The cuticle, for example, is a layer of cells overlying the vascular and sensitive true skin. From the latter, a thin, and nearly transparent, serous fluid perpetually exudes, and in this, as a nutritive plasma or blastema, the cuticular cells are formed.

Let a portion of cuticle be removed by a blister or a slight burn; the exposed surface is found to be constantly bathed with this fluid. If lightly sponged dry, the surface immediately perspires, as it were, and moistens again. The cells, first formed in this fluid, are soft and round, as seen under the microscope, in newly-formed cuticle. They are also soluble in acetic acid. They give place to similar cells underneath, and as the first formed pass upwards from the true skin, they become dry, hard, and flattened, and acquire the characters of ordinary scaly epithelium; which eventually disintegrates and desquamates from off the surface of the body. A chemical change also accompanies the maturation and destruction of cuticular cells; in this stage, they are insoluble in acetic acid.

This twofold process—formative and destructive—is ever going on; the cuticle being produced, and reduced more or less perceptibly by the decay, death, and shedding of the cuticular cells; they having previously served their function of protecting the subjacent true skin.

Molecular disintegration and death, by the constant exercise of function, may be inferred, if not seen, to be proceeding in all other tissues. But constant waste, thus induced, implies constant repair, and the reparative material can only come from the blood. This vital fluid must, therefore, present an appropriate composition for the repair of each component tissue of the body, and must also be supplied in adequate quantity thereto, as all the tissues are alike undergoing incessant destruction.

Assuming this twofold condition of quality and quantity of blood, due to the tissues severally; they, on their part, select and secrete or separate from the blood-vascular system, as the common reservoir, that kind and quantity of plasma which is appropriate for their individual nutritive maintenance. The blood is thus left reduced in quantity, and, moreover, deprived of those constituents which have entered into the formation of the tissues. But, as each tissue draws its own particular nourishment, the residual mass of blood, in circulation, becomes relatively adapted, in quality, for the proper nourishment of other tissues, of dissimilar composition. The tissues, severally, in their functional relation to blood-elaboration, are thus excreting organs.

The blood is renewed in quantity, and further maintained in quality, by the co-operation of other functions,—digestion, excretive secretion, and respiration; while its circulation is regulated by the agency of the nervous system. Again and again is this fluid, replenished and renovated, distributed to every part of the body, each tissue claiming and retaining that quantity of the common pabulum which may be necessary, and selecting those ingredients which enter into its own formation, to repair its waste and thus maintain its substance.

*Growth and Development.*—It will be obvious that any increased

nutritive demand, beyond that of mere maintenance—as by Growth, necessarily implies at least an increased supply of blood to the part undergoing this change, and perhaps also a different quality of blood to meet any such additional requirement. Indeed, ever moving and vibrative as are the leaves of an aspen tree even on a breathless summer's day, so likewise oscillatory is the nice adjustment and equilibrium of nutrition. The balance of maintenance could never be continued from hour to hour, scarcely from minute to minute, without a varying capacity in the circulatory system to satisfy ever-varying demands. This provision would seem to be brought into action by nervous influence. For, not a sensation thrilling, not a thought inspiring, not an emotion agitating ever so gently, but forthwith there is a flush of arterial blood with life-giving energy; manifesting the wide-spreading agency of the nervous system. In some instances, this rush of blood is visible, as in blushing. By analogy, it is probable that any act of volition in like manner relaxes and enlarges the capillary vessels of the muscle or muscles to which it is directed, through the medium of the nervi-vasorum. The flow of nervous influence, or vis nervosa, which excites contraction of the voluntary muscular fibres, would thus simultaneously relax the involuntary fibres of the smaller vessels. The waste of muscular tissue incurred by each slight momentary movement, and, therefore, more so by continued exercise, would consequently be repaired by an adequate flow of blood. Proportionate also to the act of volition as is the exercise and accompanying waste, so also may be the enlargement of the nutrient vessels, and consequent flow, or supply, of blood. Determination of blood it might then be called. But, this influence of the nervous system by volition is a physiological probability only, not a fact, as yet actually demonstrated.

*Development* contrasts with growth, in representing the quality, as well as quantity, of structure produced. But the two are concurrent and co-equal manifestations of the formative power, in healthy Nutrition.

It would appear that emotional influence is not limited to apportioning the supply of blood, and thence the quantity of growth or the size attained by a part subject to such influence; the *quality* or kind of growth produced, is also, in a measure, regulated thereby. For example, a fatty tumour was removed by Mr. Lawrence, several years ago, from a woman's shoulder; and when the wound had healed soundly, she imagined the tumour to have been a cancer, and that it would return. By accident, Mr. Paget saw her some months afterwards, and she had a large and firm painful tumour in her breast, which was not removed, for its nature was obscure and her general health unfavourable. Some months subsequently, having become Mr. Paget's patient at the Finsbury Dispensary, her health had much improved, but the hard lump in her breast still remained, as large as an egg, and just like a portion of indurated mammary gland. She was assured by Mr. Paget that her supposed cancer would disappear; and it did become very much smaller, without any help from medicine. As this tumour had arisen under the influence of fear, so it very nearly subsided under that of confidence. The patient was lost sight of before the tumour had been completely absorbed.

In this summary of the process of Nutrition, we observe a co-operative relation subsisting between its essential conditions:—textural changes; and the blood, in quality and quantity, as representing the nutritive material; accessory to which are the blood-vessels which convey the blood to the part nourished; and the nerves in connexion therewith,

which further regulate the supply. The accessory character of the two latter conditions is also evinced by the fact of Nutrition taking place in comparatively avascular textures, and those which are destitute of nerves; as cartilage. Thus then is Nutrition maintained; and we also observe in these conditions adequate provision for the extra demands of Growth and Development, whereby blood is duly determined to textures or parts undergoing this twofold physiological change.

*Repair* of texture, after destruction by injury or disease, is subject to the same conditions. The processes of primary adhesion, immediate union, suppurative granulation,—with perhaps secondary adhesion, and scabbing, as described in subsequent chapters, may therefore be properly associated with this general consideration of the physiology of Nutrition.

INFLAMMATION is another modification of Nutrition, the same elements co-operating. This process can be observed when it takes place in textures on the surface of the body, as the skin; and it is best illustrated when occasioned simply by a burn or other injury, rather than when induced by the operation of a blood-poison, as in erysipelas, boil, or carbuncle; which are specific and complicated illustrations of inflammation.

(1) *Textural Changes*.—The twofold nature of the textural changes in Inflammation, is the same as in healthy Nutrition; but the textural productiveness and the destruction of texture, are both increased, and the process proceeds more rapidly. Hence, the products are not only increased in quantity, they are also imperfect structural conditions of textural elements, by various degrees of arrest of their development; such as exudation and pus-corpuscles, coagulated fibrin with plastic corpuscles, granular matter, and serum; while the débris or waste matter of the texture is apt to accumulate.

In virtue of its increased productiveness, inflammation differs from nutritive-maintenance, and is allied to growth; but in virtue of its rapidity, the process is so hurried on, that more is accomplished in a given time, and consequently the products are imperfectly developed. Accelerated Nutrition would therefore seem to be an appropriate name for Inflammation, as at once expressing its nature and distinctive character.

(2) *State of the circulation of blood*, and of the *blood-vessels*, in relation to, and in, the part inflamed.—This element of inflammation necessarily pertains to vascular textures; nevertheless, comparatively avascular textures, such as cartilage, which are nourished by imbibition, are affected by the circulation of blood in the adjoining texture, whence they derive their nutritive material as the source of supply.

The blood current to, and from, an inflamed part, through the arteries and veins respectively, is increased in quantity, force, and rapidity; so also it would appear to be primarily increased in the capillaries of the part, but secondarily it becomes stagnant, a condition known as the *stasis* of the circulation in those vessels. The arteries, veins, and capillaries all apparently become enlarged.

Enlargement of the arteries, with increased flow of arterial blood through them, constitutes *determination* of blood; enlargement of the capillaries, with stagnation or accumulation of blood in them, constitutes *congestion* of blood; the enlarged veins transmitting the increased current of blood, through collateral capillaries.

In inflammation, the presence of determination of blood, subsequently of congestion, and possibly the co-existence of both these vascular con-

ditions, are facts, which have been more or less established by the following experimental observations.

(a) *Arterial and Venous Circulation*.—The arteries towards an inflamed part throb with increased pulsation, while the veins therefrom are turgid. It might appear that the former are beating with blood apparently rebounding from some obstruction in advance, and that the latter become turgid with stagnant blood. But experimental observations demonstrate the accelerated rapidity and force of the blood's motion to, and from, an inflamed part.

Let an artery toward a part inflamed be divided, and the blood is seen to be ejected to a much greater distance than that from an artery of the same size and distance from the heart, but not contiguous to an inflamed part.

This increased propulsion was noticed by Dr. John Thomson,\* when the arteries of a finger were divided in whitlow, and when those of the prepuce, much inflamed, were cut in the operation for phymosis. More exact, because comparative and otherwise complete, was the observation of Mr. Lawrence.† One hand of a patient being inflamed, venesection was performed, at the same time, and in a similar manner, in both arms: the vein from the inflamed hand yielded about three times more blood in a given time than the vein from the uninflamed hand. The blood's motion from the part was increased.

Enlargement of the arteries leading to an inflamed part, in the human subject, is rendered probable by Hunter's well-known experiment on a rabbit. Hunter froze the ear of a rabbit, and thawed it again; acute inflammation began, with increased heat, and considerable thickening of the part. The rabbit was killed when its ear was at the height of inflammation. The head was then injected, and the two ears were removed and dried. The uninflamed ear dried clear and transparent; its vessels were distinctly seen ramifying through its substance; but the inflamed ear dried thicker and more opaque, and its arteries were considerably larger.

(b) *Capillary Circulation*.—The state of the capillary circulation in inflammation, and the condition of stagnation or stasis, has been observed in the transparent parts of certain animals, chiefly in the web of the frog's foot, and in the bat's wing. Conclusions drawn from such data relative to the human organism, are inferential only, the physiological and structural conditions being dissimilar. Yet these inferential conclusions represent the remainder of what is known respecting the nature of inflammation, in the human subject.

Determination and congestion of blood, are, according to some observers, said to co-exist at the seat of inflammation. Dr. C. J. B. Williams maintains this view; and also that the resulting compound state-inflammation may originate either in determination or in congestion, or in the concurrence of both simultaneously.

To illustrate the origin of inflammation by the concurrence of determination of blood and congestion, Dr. Williams adduces observations made on the web of the frog's foot. "If," says he, "a strong irritant, as a grain of capsicum, or a minute globule of essential oil, be applied to the web, all its blood-vessels speedily become enlarged; those most irritated

\* Lectures on Inflammation, 1813, p. 67.

† Lond. Med. Gaz., vol. v., 1829.

are very large and red, and the blood in them is stagnant and coagulated, contiguous vessels are also very large, but less red, and the motion of the blood in them is slow, and often in pulses or oscillations; whilst in vessels beyond, the enlargement of the capillaries is less considerable, but that of the arteries is obvious, and the current of blood is very rapid."\*

This state of co-existing congestion and determination of blood, as resulting from over-irritation of the web of a frog's foot, may be inferred to occur also in the human subject. But in other animals than the frog, congestion occasioned by venous obstruction, produced artificially, actually averts determination of blood: therefore, experimental observation equally justifies the inference, that diminished motion of blood cannot be, in the human subject, an essential part of inflammation—a process which certainly implies determination.

Thus, the experiments of Macartney appear to me conclusive evidence that determination of blood is prevented in rabbits by congestion arising from venous obstruction. The most remarkable circumstance, observes this authority, with respect to congestion, and the one which has not hitherto been described, is that arteries found in a congested part are smaller than their natural size.

Both the jugular veins of a rabbit were ligatured; the animal died apoplectic, and upon examining the vessels of the ears, the veins which lie towards their outer edge were found greatly enlarged and gorged with dark blood; but the artery which runs in the centre of the ear was reduced very much below its natural size, so that it appeared as a mere line.

Another experiment showed the instantaneous effect of arresting the venous circulation. The mesentery of a young rabbit was exposed, and the trunks of several mesenteric veins having been tied, their corresponding arteries contracted immediately in the most palpable manner and to a very small size, as if, significantly adds Macartney, taught by their organic instinct that blood should not be permitted to go where it must immediately return.\*

The causes of congestion of the capillaries in inflammation, are said to consist in the state of these vessels, and of their contained blood; the former becoming dilated, lengthened, and tortuous, as the result of their weakness and inelasticity from over-irritation; the latter being an impacted state of the red-corpuscles, and increased production of the pale-corpuscles, which are also more adhesive than in health, and cling to the sides of the vessels.

But, equally untrustworthy as are experiments on the frog's foot, the bat's wing, and other transparent parts of animals, to determine whether congestion be an element of inflammation in the human subject, are similar observations to ascertain the condition of the capillary vessels and of their contents in the state of inflammation.

Assuming the experimental observations of Dr. Williams on the web of the frog's foot to be accurate, the dilatation, lengthening, and tortuosity which he describes in respect of these vessels, are at the best but data for conclusions, indirectly—grounds of probability only—as to the condition of the capillaries during inflammation in any part of the human body. No one has ever seen the appearances of the capillaries in the human sub-

\* On Inflammation, 1838, p. 141.

ject, either during inflammation or in the healthy living condition; nor can we follow with faith in the assumption that because red blood-discs become impacted, and white blood-corpuscles are apparently more abundantly developed and more adhesive than usual, clinging and lingering round and round on the walls of capillary vessels in the web of the frog's foot; therefore there is a similar blockade of these discs and waltzing of these corpuscles in the capillaries—say of the conjunctiva of the human eye when inflamed. In point of fact, the capillary circulation of a warm-blooded animal under the same circumstances does not present these appearances. Paget and Wharton Jones both watched and failed to discover any undue display of white corpuscles in the bat's wing, and the former authority attributes the large proportion of these corpuscles noticed in the frog to an unhealthy condition of this animal.

According to Professor Lister's experiments, inflammation consists apparently of a series of changes, in order as follows:—(1) A suspension of the concurrent exercise of function among the minute elements of the tissue. (2) Derangement of the blood, which, in the vicinity of the impaired tissue elements tends to assume the same character as blood always acquires when in contact with ordinary solid matter, and which renders it unfit for transmission through the blood-vessels. A return of the tissue elements to their usually active state will be associated with a restoration of the blood to a condition fitted for circulation. (3) The arteries are narrowed, and the blood flows through them with greater rapidity. (4) The same vessels subsequently become enlarged, and the current of blood is slower, although uniform. (5) The flow of blood becomes irregular. (6) All motion of the blood ceases, and complete stagnation ensues. (7) The liquor sanguinis may be exuded through the walls of the blood-vessels, sometimes accompanied by the extravasation of blood-corpuscles, owing to rupture of the capillaries.

In tracing the process of Inflammation, it is difficult to determine the order of succession in the changes which essentially constitute this process. The question of priority, therefore, on the part of the textures or the blood, is doubtful. Whether an increased textural productiveness and consequent demand for nutritive material, induces an extra flow of arterial blood towards this focus of accelerated nutrition; or whether a determination of blood solicits the formative power of the textures to more active, albeit abortive operation?

The latter view, originally advocated by John Hunter, long held undisputed acknowledgment in the schools and in medical literature; before the textures were discovered, so to speak, by Bichat, and before the grand and fertile theory of cell-development introduced by Schwann and Schleiden. But the independent vitality of the textures in relation to the blood, a physiological doctrine probably entertained by Haller, was subsequently extended to pathology by Hebreustreit, Burdach, Alison, and others; while, in respect to Inflammation especially, this doctrine is strenuously advocated with great originality of argument by Virchow,\* and exclusively adopted by Mr. Simon,† and other pathologists in recent works.

For the discussion of any other doubtful points respecting the intimate nature of Inflammation, and more particularly as investigated in animals,

\* Cellular Pathology. Trans. by F. Chance, 1860.

† System of Surgery. Ed. by T. Holmes, 1860, vol. i, p. 6.

the reader is referred to abundant sources of interesting information in the writings of Wilson Philips, Kaltenbrunner, Gerber, Gendrin, Müller, Lebert, Alison, Henle, Addison, Gulliver, Wharton Jones, C. J. B. Williams, Bennett, Paget, and Joseph Lister.

*Signs.*—The local signs of inflammation are redness, heat, swelling, and pain; the first three being objective phenomena, pain, a subjective symptom, and there is also some functional disturbance or loss of functional power in the part affected.

(1) *Redness* is a sign of inflammation, owing to the determination of arterial blood; but the development of this sign will be proportionate to the number of capillary vessels pervading the part, and the extra flow of blood through them. The colour, a florid hue, varies according to the arterial or venous character of the blood, and as shaded by any intervening texture; or it may be entirely unseen through the depth of integument concealing the engorged vessels. Their engorgement, or hyperæmia, presents different shapes, according to the peculiar anatomical arrangements of the capillaries in the texture or part. Hence punctiform, stellate, arborescent, maculiform, or spotted, and uniform blush-redness, are frequently recognised, as in the skin and mucous membranes which are open to inspection.

Redness, such as I have described, is the earliest announcement of inflammation, and also its most exact indication, being invariably present, even when unseen, a sign of no other kind of hyperæmia, and the measure of its own. The exceptional case of a growing part—*e.g.*, the gravid uterus, having similar redness, scarcely invalidates the general fact that this sign is, otherwise, peculiar to inflammation. Nor does its exceptional absence in extra-vascular tissues—*e.g.*, cartilage and the cornea, affect the otherwise general constancy of this concomitant hyperæmia. Even in such cases the adjoining textures exhibit its characteristic appearance, as by a zone of redness around the cornea, in corneitis, and increased vascularity of the adjoining bone, in inflammation of cartilage. In either case, the seat of hyperæmia coincides with the capillary plexus which is subservient to the healthy nutrition of the part inflamed.

Redness from the development of new vessels in an inflamed part is not an early occurrence, but a consequence of the process of inflammation.

(2) *Heat* is another local sign, partly due to the determination of blood; as such it is proportionate thereto, and to the number of vessels through which the extra supply of arterial blood is passing. But the increase of temperature will be perceptible only according to the superficial situation of the inflamed part, and the facility with which heat is transmitted through any intervening textures.

Is heat generated by inflammation? The flow of arterial blood, and therefore of red blood-corpuscles charged with oxygen, may possibly generate heat. Yet the experiments of John Hunter show that the temperature of an inflamed part never rises more than two or three degrees, and scarcely, if ever, above the average heat of arterial blood—say, from ninety-eight to one hundred degrees Fah. On the other hand, the more recent “thermo-electric” observations of Mr. Simon\* and Dr. E. Montgomery are apparently conclusive on this point—that an inflamed part is

\* System of Surgery, edited by T. Holmes, 1860. Vol. i., Inflammation, by J. Simon, p. 42.

no mere passive recipient of heat, but is itself actively calorific. For among the observed results are these:—

“That the arterial blood supplied to an inflamed limb is found less warm than the focus of inflammation itself.

“That the venous blood returning from an inflamed limb, though found less warm than the focus of inflammation, is found warmer than the arterial blood supplied to the limb; and

“That the venous blood returning from an inflamed limb is found warmer than the corresponding current on the opposite side of the body.”

Granting, then, that the inflammatory process unquestionably involves a local production of heat, “to interpret this fact,” adds Mr. Simon, “is perhaps, in the present state of physics, not possible.”

Whatever be the source of increased heat, it continues with the inflammation, unlike the transient warmth of blushing, or other non-inflammatory determination of blood.

Respecting its diagnostic value, the increased heat arises at the same time as the redness; it is an equally early, if not an equally exact sign of inflammation.

(3) *Swelling*.—The persistence of inflammatory determination of blood is accompanied with the appearance of lymph and serum, and consequent swelling in a greater or less degree; unlike the issue of that temporary distension of the vessels, which ordinary determination of blood denotes.

By this persistent increased flow of blood, the surcharged vessels would appear to be gradually relieved by effusion of the liquor sanguinis.

Virchow\* ventures to advance the hypothesis, “somewhat bold perhaps, though perfectly able to sustain discussion: that, fibrin generally, wherever it occurs in the body external to the blood, is not to be regarded as an excretion from the blood, but as a local production. Nobody,” he alleges, “has ever been able by the production of a mere change in the force of the current of the blood to induce the fibrin to transude directly, as it is wont to do in certain inflammatory processes; for this some irritation is always required.” Accordingly, in respect of inflammation, Virchow regards fibrin, not as an exudation or effusion from the vessels by persistent (inflammatory) determination of blood, but as “an educt from the vessels, in consequence of the activity of the histological elements themselves.”† Professor Bennett‡ suggests that the tissues attract the fibrin, which, however, pre-exists in the blood.

The engorged vessels themselves occasion some degree of swelling of the part; an increase proportionate to the vascularity of the part, and to the degree of turgescence of its vessels. Full-blooded internal organs become most swollen in this way, such are the lungs, liver, spleen, and kidneys when inflamed. But with persistent engorgement further enlargement ensues by effusion, and the situation, size, shape, and physical characters generally of this swelling, will, for the most part, depend on the kind of structure in which it takes place.

Liquor sanguinis is readily effused into the constituent cellular texture of the organ, or part inflamed, and therefore most readily into the substance of loosely parenchymatous organs; frequently, moreover, the most vascular, such as those just enumerated. Lymph and serum overflow into

\* Cellular Pathology. Trans. for Syd. Soc. by F. Chance, 1860, p. 162.

† Ibid., p. 386.

‡ Clin. Lectures on Medicine, 1858, p. 133.

cavities—*e.g.*, into serous membranes and synovial sacs. These and similar structures solicit the overloaded vessels to relieve themselves, and their size becomes enlarged, in a corresponding measure, by inflammation. Witness hepatized lungs from pneumonia in its second stage—immense enlargement of the liver from chronic inflammation; enormous increase of the spleen, forming the ague-cake by an analogous process; and the immense size to which the kidneys attain by chronic nephritis and Bright's disease. Phlegmonous erysipelas—engaging, as it does, the subcutaneous cellular tissue deeper and deeper—is characterized by considerable swelling. Witness the opposite results in tight unyielding textures—such as effusion beneath fasciæ and in fibrous textures generally, and an abscess formed in the substance of bone, but unattended with any perceptible swelling, and suspected only by the intense and unremitting pain it occasions. Certain textures allow of an intermediate amount of swelling between the extremes presented by cellular and fibrous tissues. Such are the degrees peculiar to the skin and mucous membranes. Of the latter I may mention pulpy thickening of the large intestine in cases of chronic dysentery, while swelling in some measure of the skin is one feature of most of its eruptions, however otherwise diversified their appearance may be—as rashes, scales, papules (pimples), vesicles, pustules; and most conspicuously this is the character of solid tubercular swellings, such as occur in secondary syphilis.

The shape of inflammatory swelling is also a mixed result, principally due to the kind of structure into which effusion takes place; partly, however, to the kind of matter effused. If thin serum, the swelling will be fluid, fluctuating, and diffused; if coagulating lymph be poured out, it will be more solid and circumscribed. I shall not attempt to describe the various degrees of density or consistence which inflammatory swelling presents, as resulting from the combined influence of the kind of matter effused, and that of the receiving structure. These alterations may be of two kinds: softening, chiefly in connexion with acute inflammation, and induration, chiefly in consequence of chronic inflammation.

The diagnostic value of inflammatory swelling is not equal to that of redness. It is necessarily a later sign than redness, which always precedes effusion by an important and often appreciable period of time. Iritis is announced by injection of the ciliary arteries and a zone of redness around the iris, before the perilous effusion of lymph. Erysipelas spreads with a red blush before the disorganizing engorgement of the subcutaneous cellular tissue. Regarded as an exact sign, although some degree of swelling invariably follows inflammatory determination of blood, and although the nature of an obscure swelling is assured, if not by its physical properties, at least by puncture, and if necessary by further examination with the microscope of the material of the swelling; yet these guarantees of identity are the only unequivocal advantages of this sign. Unlike redness, it is no measure of the degree of inflammation. The most intense may produce a trivial swelling in an unyielding texture, and a trivial degree of inflammation will soon exhibit considerable swelling in a loose tissue.

Subject to these disqualifications, swelling is the more valuable sign, practically speaking, of inflammation. It can be discovered when the redness cannot be seen. In all superficial textures and parts, swelling can be readily detected. The skin, cellular texture, muscles, periosteum, bone, blood-vessels, and lymphatics, and the component tissues of the

joints severally present each a characteristic swelling when inflamed. Certain internal organs are also open to examination—*e.g.*, the pelvic viscera, excepting the bladder. Thus, inflammatory enlargement of the prostate, or the uterus, and thickening of the rectum, can be felt, and possibly seen. Certain other organs are indeed beyond the reach of vision and the direct application of the hand, yet the ear can then detect effusion and swelling by means of percussion, as of the liver, gastrointestinal canal, and spleen; and this may be aided by auscultation, as of the heart and lungs.

(4) *Pain*.—Observe, the influence of swelling. No sooner has the first contribution toward swelling been made by persisting distension of the vessels of the inflamed part, than pain, or at least exalted sensibility, is induced by the blood's influence on the nerves of that part. The degree of pain from this cause will be regulated by both the elements which determine the amount of hyperæmia, that is to say will be proportionate to the determination of blood, and the number of vessels in the part; but the number of sensory nerves affected will further apportion the degree of pain. As swelling ensues from effusion, the same conditions which represent the degree of tension, will also measure the intensity of the pain. Thus a more solid, and therefore circumscribed effusion of coagulating lymph, underneath an unyielding texture, such as a fibrous membrane—*e.g.*, the fascia-lata, or a fluid similarly circumstanced, as an abscess in the substance of bone, are aggravating conditions inducing the most severe and unremitting pain; while a more fluid serous effusion into a loose texture such as the cellular tissue, say of the arm-pit, allows of a more considerable accumulation without much pain, and will then be more tolerable. Pain is also attributed to structural change in the nerve-fibrils of the inflamed part. (Simon).

The character as well as the degree of pain accompanying inflammation, is equally diversified. A burning pain in erysipelas, whence the popular name of this disease—St. Anthony's-fire. A scalding pain in inflammation of the rectum, during evacuation of the fæces. Chronic rheumatism and lumbago are attended with the dull aching pain of inflamed fibrous and muscular tissues; gout, with a wrenching pain; abscess in bone, with an unremitting burrowing pain; inflammation of the dental periosteum-periodontitis, with a throbbing pain. In other parts this character of pain is the known forerunner of suppuration. Parts endowed with but little sensibility in health, generally become acutely sensible when inflamed; as fibrous textures and bone, including the teeth; the intestinal canal in enteritis, the pleura and peritoneum respectively, when inflamed. Parenchymatous organs likewise acquire exalted sensibility, as manifested by the heavy, oppressive pain of pneumonia. Organs of special sense are for a time quickened by inflammation, and convey their own sensations but too keenly. The ear becomes too susceptible of sound, and iritis begets intolerance of light.

*Reflected* pains in distant parts are not uncommon symptoms of inflammation. Pain in the inner side of the knee may emanate from inflammation of the hip-joint; in the glans penis, from cystitis; in the testicle, from nephritis; under the right shoulder-blade, from hepatitis; and under the left scapula from gastritis. Reflex motions may be excited in like manner: Sneezing, by catarrh; coughing, by bronchitis and pneumonia; vomiting, by gastritis: and (reflex?) micturition, by cystitis.

The diagnostic value of pain is comparatively little. The pain of inflammation being chiefly due to swelling, is scarcely an earlier sign. It is also the most inexact sign; pain may be absent in true inflammation, and present without; and is rather a measure of the kind of swelling than of the degree of inflammation. By itself, therefore, pain has little diagnostic importance.

(5) The *function* of the organ or texture affected, undergoes certain changes, which constitute additional local symptoms of inflammation. They may be described in general terms, as exaltation of function, followed by its depression, and various perversions of function having an intermediate character. Thus, with inflammation of the brain; delirium, increased sensibility and convulsions, are succeeded by stupor and paralysis. Inflammation of the spinal cord presents similar symptoms; excepting of course any modifications of purely cerebral functions. With nephritis, the secretion of urine is first increased, then diminished; and so with regard to other secreting organs. In pneumonia, dyspnœa represents increased respiratory effort, but this is attended with imperfect aëration of the blood and the retention of hydro-carbonaceous matter. Accumulation of excrementitious matters in the blood is the most serious consequence of inflammation affecting any specially excreting organ; as the kidneys or skin.

By itself, pain has, we have seen, but little diagnostic importance; yet from this point we can trace the origin of inflammatory fever.

*Constitutional Symptoms—Inflammatory Fever.*—The phenomena of this fever are briefly these:—the heart's action is excited, the pulse becoming more forcible and frequent than usual, and in some cases, less compressible; the skin is dry and hot, the urine scanty and high-coloured, the tongue furred, the bowels probably constipated, and the fæces dry and hard; thirst and inappetency, weakness with general nervous excitement, —restlessness, sleeplessness, and hurried respiration, are also primary phenomena. Hence, the vascular, secretory, and nervous systems, are together engaged in a constitutional disorder—symptomatic of the local inflammation.

*Febrile urine* exhibits physical characters and chemical peculiarities of peculiar importance. At first, it has a deep red colour, strong urinous odour, super-acid reaction, high specific gravity; and the quantity secreted in a given time is diminished. These alterations are chiefly owing to a reduced proportion of water, rather than of solid constituents in the urine, which has thus become concentrated. But the inorganic salts, especially the chloride of sodium, are diminished, both absolutely and relatively; while, uric acid and the urates are increased. Even when urates are not deposited, there is always an excess of uric acid. Urea is increased in some cases, and probably diminished in others. The greatest quantity present would appear to be in meningitis, and an excess is found during exudation; but urea is diminished during resorption, in pneumonia, pleurisy, and in acute rheumatism, especially if accompanied with endocarditis. Extractive matter is generally increased, and lactic acid is often present. Occasionally, a small quantity of albumen is found, but only for a short time. As inflammatory fever declines, the urine deposits a lateritious or brick-dust coloured sediment, more or less abundant, consisting of urate of ammonia.

The quantity of sweat is much diminished during inflammatory fever, but its chemical composition at that time is not well understood. Ulcers,

also, which have been discharging freely become dry. The flow of saliva is less free, and the tongue furred. This appearance arises from a material of whitish yellow or brown colour and firm consistence, overlaying the posterior and middle portion of the tongue on its upper aspect, and adhering closely. It cannot be removed altogether by scraping, but as the fever declines it is shed spontaneously. If, says Dr. Thomson, this furr arose from the nature of the saliva secreted, then, instead of being found only on the upper, middle, and posterior parts of the tongue, we should find it incrusting the whole internal surface of the mouth. It is probably secreted from the papillæ to which it adheres. A similar appearance arises from irritation of the stomach, without any fever at all. Discrimination, therefore, is necessary, by considering whether other symptoms concur.

*Blood.*—The Blood undergoes certain very important alterations in inflammation, and which are of two kinds; namely, in respect to its vital properties, and therefore as affecting its coagulability and coagulation; and in respect to its chemical composition.

The altered vital properties of the blood comprise: an increased tendency to coagulation, and to the separation and contraction of the fibrin in a free state. The phenomena known as the buffy coat and sizzly blood are thus produced. These appearances can be understood by comparing the changes which take place, as observed in the coagulation of healthy blood.

Let a pint of fresh-drawn blood be exposed in a shallow basin; immediately a vapour, having a faint odour, arises, which (*halitus*) was first noticed by Haller. In about four minutes a pellicle appears at the edge of the vessel, soon extending over the surface of the blood and down the sides of the vessel. It pervades the whole in about eight or nine minutes. The fluid blood is thus converted into a jelly. But in a variable period, from seventeen to twenty minutes, or much later, this jelly begins to shrink away from the sides of the basin, and the colourless, transparent serum exudes—a process which, continuing for several hours, or even days, at length leaves a blood-red clot, floating about in limpid serum. And what is this clot? The *fibrin* of the liquor sanguinis, which has spontaneously solidified into fine homogeneous filaments, interwoven like felt, and which has caught and involved the red corpuscles. They also have spontaneously aggregated, their disc-shaped surfaces cohering side by side, and forming *rouleaux*, like piles of money, which then connected themselves into an irregular network; the shrinking of this fabric, intertwined with that of the fibrin, expressed the serum, and thus aided the solidification of the clot. Two constituents, therefore,—the fibrin and red discs,—together spontaneously aggregate to form the clot, which consists of woven filaments, involving the net of red-discs. The expressed serum is structureless. The pale or colourless corpuscles are irregularly distributed throughout the clot and serum.

These changes are represented in the following table.

Fluid Blood.	{ Liquor Sanguinis. Corpuscles.	{ Serum. Fibrin.	} Clot.	{ Coagulated Blood.

The experimental observations of Dr. B. W. Richardson\* apparently demonstrated that this process of coagulation is essentially associated with

\* The Cause of the Coagulation of the Blood, 1858.

the elimination of ammonia—a most significant fact. More recently however, the observations of Professor Lister\* tended to negative this conclusion; and it is, I believe, regarded as no longer tenable.

If the blood, freshly drawn as we have supposed, be inflammatory, its coagulation then presents a clot, the upper portion of which is pure fibrin, of a tawny-yellow colour, and known as the *buffy coat*. This, therefore, consists of a portion of fibrin, which has coagulated apart from the mesh formed of red discs. And what is the immediate cause of this kind of clot? Obviously, that the red discs separated and subsided from the liquor sanguinis before the fibrin began to coagulate. How does such isolation arise? Possibly in either of two ways, or by a concurrence of both. The fibrin may coagulate so slowly as to allow time for the blood-discs to separate and subside. But Dr. Stokes† watched the coagulation of inflammatory blood in twenty-seven cases. In fifteen of them the buffy coat formed; in the remaining twelve it did not. In four of these twelve samples of ordinary coagulation, it began only at the end of eight minutes after venesection, and in other three of this series not until after twenty to forty minutes had elapsed—making a range between the two extremes of from eight to forty minutes. This delay of coagulation gave ample opportunity for the red discs to escape from the fibrin during its solidification; yet they did not subside, and the usual red clot formed. On the other hand, in twelve of the fifteen samples of buff-forming coagulation, the yellow clot of pure fibrin formed in only five minutes, and in the remaining three it was delayed only to ten minutes; so that, during this comparatively short period of five or ten minutes, the red particles had separated and settled down, leaving the buff-coloured fibrin free and floating. Slow coagulation, therefore, does not explain the production of the buffy coat.

The only other active element in coagulating blood is the mesh-forming discs; and how do they behave in freshly-drawn inflammatory blood? They individually possess undue power of aggregating (H. Nasse), and the net thus wrought has also undue power of contracting (W. Jones), whereby the serum is more effectually expressed from its meshes. This fabric, therefore—the component particles of which have individually greater specific gravity than the serum—has now even greater weight, bulk for bulk, and being formed earlier than usual, subsides in the serum before the fibrin has fairly solidified, or perhaps before this more essential element of the clot has begun to coagulate. John Hunter seems to have anticipated this view of buffy blood, and Schroeder Van der Kolk, with other observers, have corroborated it.

Combining all these observations—formation of the buffy coat seems to imply an increased separation and contraction of fibrin in a free state, rather than its increased power of separation and contraction, and that the blood-discs are the initiative and active element in the process of buff-forming coagulation.

Slow coagulation of the fibrin will, however, favour this result, by allowing more time for the gregarious blood-discs to flock together and exercise their function as a contracting mesh. If, therefore, the blood be artificially preserved in a fluid state, by adding serum to above its proportion, thereby delaying coagulation; the red-discs aggregate and subside, and the buffy coat is presented.

\* Lecture before the Royal Soc. Lond., *Lancet*, 1863, Vol. ii., Nos. vi. vii.

† *Brit. and For. Med.-Chir.-Rev.*

Probably all the causes I have mentioned concur to produce this result, and that as they prevail more or less during the act of coagulation so is the buffy coat of pure fibrin more or less completely established.

The earliest intimation that blood is about to undergo this kind of coagulation, is the appearance of a violet tint, not unlike the bloom of black Hamburg grapes, on the surface of the exposed blood. This appearance was, I conceive, noticed by Hunter, and regarded by him as due to the red particles shining through a thin layer of buff-coloured lymph, just as blood in the veins gives a similar tint when viewed through the skin. The tint will therefore vary as the layer of fibrin becomes thicker. Coagulation proceeding, if the mesh of red particles separate and subside from the fibrin, but yet slowly and incompletely, and if the free fibrin but imperfectly solidifies and contracts, then a loose *sizy* clot is produced, resembling a solution of isinglass, attached to the sides of the vessel, and scarcely trembling when shaken. If, again, the separation and contraction of pure fibrin be more complete, a flat, yellow buff-coloured cake is produced, swimming in serum; but the under portion of this clot is red as usual by admixture of the red discs. If, again, the separation and contraction of fibrin be still more complete, the fully-formed, solid, and buff-coloured clot is presented, withdrawn from the sides of the vessel, and probably concave or *cupped* on its upper surface: the lower portion of this clot having formed more slowly, has therefore contracted more strongly, and drawn down the central part of its upper aspect. The blood, or rather clot, is buffed *and* cupped. Even in such case the red particles and fibrin do not completely separate. In thirty samples of buffed blood, carefully inspected by Dr. Richardson,\* he never failed to find red discs in the lower portion of the clot, and in many instances this red lower portion had the consistence of ordinary coagulum.

The *diagnostic value* of these appearances is not absolute. Invariably present with inflammation, they are also present in other conditions affecting the blood. Coagulation exhibits the buffy-coat notably in pregnancy, and other conditions attended with an excess of fibrin in the blood; and both the buffed and cupped appearance may proceed from slow coagulation, without any change in the constitution of the blood itself, as when this fluid is drawn quickly, in a full stream, and received into a narrow deep vessel. Conversely, exposure, as by a trickling stream, into a shallow vessel, hastens coagulation, and thus prevents these results.

Besides these deviations in the process and product of healthy coagulation, inflammatory blood is found to have undergone certain alterations in respect of chemical composition. Its constituents, no less than their properties and endowments, are perverted. Becquerel and Rodier enumerate the following alterations in the blood of acute phlegmasiæ:—

1. An increased proportion of fibrin.
2. A decrease of globules.
3. A decrease of albumen of the serum.
4. An increase of fatty matters.
5. A decrease of soda and soluble alkaline salts.

In point of practical interest, the importance of all these chemical changes appears to concentrate in the influence they exercise on the separation of the fibrin, and its coagulability in a free state.

Alkaline salts in excess are well known to retard coagulation, and a

\* Op. cit., p. 335.

decrease of the soda and soluble alkaline salts will have the opposite effect. Less time than usual is then allowed for the blood-discs to subside, and so far the formation of the buffy coat is not promoted.

An increased proportion of fatty matter will probably favour the early separation of pure fibrin, by inducing it to rise with such matter to the surface (of the blood drawn), and leave the red discs below.

A decrease of the albumen of the serum will have a similar effect, by directly diminishing the specific gravity of this fluid, so that the blood-discs sink more readily. The mean specific gravity of the serum in the phlegmasiæ generally, is estimated by Becquerel and Rodier at 1027·0; and although, according to Nasse, that is about the average in health, yet the specific gravity of serum in inflammations frequently declines below the mean of 1027. And this is due to the proportion of albumen being reduced below the healthy average of 80 parts in 1000, to 73·35, and even as low as to 64·84. It was formerly stated by Gendrin\* that the albumen rose to about twice its proportion above the standard of health. The decrease noted is in a direct ratio to the increased proportion of fibrin.

So also the blood-discs decrease in quantity proportionately to the increase of fibrin (Simon), and this reduction will facilitate their complete separation—the more so, since, by undue aggregation of the discs, their combined specific gravity preponderates even more than they do individually.

Lastly, the increased proportion of fibrin above the average of two to two and a half parts in 1000 of blood, contrasting as it does with the reduced proportion of blood-discs, is the culminating point in favour of a clot being formed of pure fibrin; and this increase, and corresponding formation of the buffy coat, was noticed by Andral and Gavarret to rise as high as ten parts in 1000 of blood drawn, in acute articular rheumatism, and in pneumonia.

The source of this additional proportion of fibrin is doubtful.

Simon suggests that the blood-discs are transformed into fibrin, and in conformity with an acknowledged physical law, that as textures waste in proportion to their functional activity, so therefore the blood-discs disintegrate more abundantly in inflammation—owing to their function as bearers of oxygen, to the various textures being overtaxed, in the more frequent transmission of these discs through the lungs, by acceleration of the blood's circulation. The flotilla of oxygen-laden cells perishes *seriatim* from overpressed service, and their wrecks are converted into fibrin. Simon's statement that the discs decrease in quantity proportionately to the increase of fibrin, harmonizes with his theory; but, against it, Becquerel and Rodier urge that this destructive change ought to take place whenever the circulation is accelerated, and therefore whenever fever exists. Yet an increased proportion of fibrin is not found in other fevers accompanied with an accelerated circulation.

Is the excessive fibrin transformed albumen? Probably similarity of composition allows of such transformation; and certainly, as the albumen diminishes in quantity, so does the proportion of fibrin increase.

Of this metamorphosis we know neither the cause nor the mechanism. (Becquerel and Rodier.)

Summarily, the coagulation of inflammatory blood—when drawn and fresh—amounts generally to this: the blood-discs, having an undue tendency to aggregate, and the net they form an undue power of contracting,

\* Hist. Anat. des Inflammations, 1826, t. ii.

more speedily sink in serum, normally of less specific gravity than the discs individually, of still less than the shrunken nets of discs; and that this separation of the discs (before coagulation of the fibrin) is facilitated by their reduced number, and by diminished specific gravity of the serum itself. The fibrin then coagulates free of blood-discs, at least in its upper portion, and rises to the surface of the serum, its ascent being probably aided by admixture with the free and floating fat.

Such is the coagulation of a sample of inflammatory blood, such the process that sample after sample of inflammatory blood undergoes.

It might therefore be inferred that the whole mass of blood, when subject to the influence of inflammation, is ready to undergo these changes, and that it would present the same alterations of chemical composition if withdrawn from the living body. But does the exalted tendency of the blood-discs to separate, and consequently of the fibrin to coagulate in a free state, prevail in the living body, and affect the whole mass of blood?

This question is highly important; for the nutrition of every part of the body, beyond that which is inflamed, must be modified by excess of fibrin in the blood—hyperinosis, and by its undue separation and coagulation. A blood-crisis bordering on the inflammatory encourages nutrition; a further degree of the same condition of blood encumbers this process with superfluous material. The former is a salutary provision to meet the exigencies of nutrition,—in growth and repair; the latter, an oppressive compulsion to overgrowth, or at least to an overflow of the redundant nutritive material. Behold, then, a reparative power; behold an impending evil.

The question proposed is at present open to much, very much, further inquiry.

*Pathology of Inflammatory Fever.*—The alterations of the blood, in connexion with inflammation, proceed apparently from the persistent local determination of blood, coupled with the increased productiveness and destruction of the textures. The increased proportion of fibrin; and the increased tendency to coagulation, and to separation and contraction of the fibrin in a free state, forming the buffy coat; are both commonly proportionate to the extent of the inflammation, and its duration in an active state. Under similar circumstances of nutrition, the same blood-conditions are induced in a greater or less degree; as during pregnancy, when the uterus is growing; and the buffed appearance of the blood is readily induced by inflammation in fast-growing children, in whom also the plastic products are then unusually copious.

Inflammatory Fever was formerly supposed to arise from the increased proportion of fibrin in the blood, or hyperinosis, as the cause of febrile excitement of the circulation, and the other functions involved. Hunter advocated this interpretation of inflammatory fever, and he gave cases, which as tested by venesection, seemed to support it.

But, the recent results of chemical analysis indicate that inflammatory fever may possibly be absent with hyperinosis, or present without it; and they certainly prove beyond doubt that the degree of inflammatory fever cannot be measured by the amount of hyperinosis. MM. Becquerel and Rodier estimate the increase of fibrin in various diseases to range from the healthy average of three to ten parts in one thousand of blood; and that a slight increase from three to five takes place in chlorosis; in certain cases of scurvy, more especially when it assumes the chronic form during

pregnancy, and in erysipelas of the face; yet surely the two first mentioned diseases are not inflammatory, nor are the ordinary constitutional symptoms of pregnancy those of inflammatory fever. On the other hand, a diminished proportion of fibrin below the average of three in one thousand was noted in scarlet fever, small-pox, and measles; but the ordinary type of these fevers is inflammatory in a high degree. Lastly, when present, the degree of this fever does not correspond with the amount of hyperinosis. A great increase of fibrin up to ten in one thousand was noticed in acute articular rheumatism, in pleurisy, and pneumonia; and a proportion varying from five to ten was also found in peritonitis, bronchitis, and severe erysipelas of the face—diseases which are accompanied with at least as high a degree of inflammatory fever as pleurisy or pneumonia.

The foregoing facts and considerations compel us to attribute the accompanying inflammatory fever to some other source than the blood; and the only other bond of sympathetic connexion between the heart and inflamed part is the nervous system.

Many years since, Abernethy suggested this channel of communication,\* and subsequently, Travers pointed out the agency of the nervous system, and drew the distinction between nervous excitement alone and inflammatory fever. Although he attributes this fever to excitement of the circulation from hyperinosis, yet he observed that the first morbid impression was upon the nervous system, and transmitted by the nerves of the part injured or inflamed to the nervous centre, and thence to the organs of circulation. In proof thereof, Travers urges the priority of nervous excitement in the development of inflammatory fever. “The *premonitory* symptoms—viz. headache, lassitude, disquietude, nausea, chilliness, and rigor are indications of the more or less troubled condition of the nervous centres; to these the alterations in the measure and force of the circulation, the permanent and sensible changes upon the internal and external surfaces, and their secretions, *succeed*—viz., quick pulse, hot skin, dryness of the mouth and fauces, furred tongue, vitiated and scanty secretions,”† &c. I have italicised two of these words in order to bring out the force of this paragraph.

Nervous excitement may stop short of inflammatory fever, or may be followed by, and remain associated with, excitement of the sanguiferous system, and either element may then predominate. Thus, “irritation may be a symptom of fever, as fever may be an effect of irritation; but they are originally and essentially distinct forms of disease, and either may exist in the absence of the other.”‡

Certain of the nervous phenomena which precede and accompany inflammatory fever are difficult of explanation. I allude more particularly to inappetency and thirst. Healthy hunger and thirst are now generally allowed by physiologists to be sensations expressing corresponding requirements of the system, rather than proceeding from conditions of the stomach. “These sensations,” observes Dr. Carpenter,§ “bear no constant relation to the amount of solid or liquid aliment in the stomach, whilst they do correspond with the excess of demand in the system over the supply afforded by the blood; and they abate by the introduc-

\* Constitutional Origin, &c., of Local Diseases, 1824, p. 3.

† Physiology of Inflammation, 1844, pp. 62-63.

‡ Constitutional Irritation, 1826, p. 493.

§ Principles of Human Physiology.

tion of the requisite material into the circulating blood, even though this be not accomplished in the usual manner by the ingestion of food or drink into the stomach." Agreeably to this physiological provision, inflammatory fever should be attended with hunger, rather than inappetency. Albumen is the pabulum most extensively demanded by the tissues for their support, and its proportion in the blood declines considerably during inflammation; yet this deficiency is accompanied with the loss of appetite. Again, the secretions are suppressed, and water, therefore, retained in the blood; yet this excess is attended with incessant thirst. Further investigation is needed to clear up these anomalies. All the other phenomena which I have enumerated as emanating from the local irritation spreading through the nervous system, are symptoms of excitement mingled with exhaustion. The *sympathetic* fever—not inaply so called—thence arising, is said to have similar types; the *sthenic*, denoted by forcible action of the heart, and a strong, hard pulse; the *asthenic*, pronounced by feeble, and rapid action of the heart, and a quick, weak, perhaps irregular pulse. But, after all the distinctions that have been drawn between these types, they are seldom well defined in Nature. Daily circumstances will modify the character of inflammatory fever during its course in the same individual.

Does the temperature of the body rise during this fever? Dr. Thomson states that it ranges from the low extreme of 94° up to 107° Fahrenheit. This is partly due at least to suppression of the perspiration, and, therefore, the retention of that heat which would otherwise pass off by evaporation from the skin. But the excited nervous system probably contributes to the production of heat. Sir B. Brodie's experiments\* show that if the encephalon be removed, the body speedily loses its temperature; a doctrine subsequently confirmed by the experiments of MM. Le Gallois and Chossat. Certain pathological observations also lead us to infer that the loss of nervous influence in any part is accompanied by a loss of temperature there.† On the other hand, the production of increased heat is attributed by Simon to chemical changes in the textures of the inflamed part, and in the blood, and thence in all blood-supplied textures. This chemically changeful state of the blood and textures, with the evolution of heat, are, by the same author, said to constitute inflammatory fever; and that its symptoms are those of this greater heat and change.

Thus far respecting the pathology of inflammatory fever, and its origin from the local irritation of inflammatory swelling.

But does this fever arise exclusively from inflammation? It has been alleged that febrile symptoms may precede the local, as in all internal inflammations arising from external cold.

To determine this question, take, for example, pneumonia. In most cases, inflammation of the pulmonary texture is consequent on the impulsion of blood by exposure to cold. The superficial blood-vessels contract under the influence of cold, the blood retires from them, and the vessels of internal organs become surcharged or congested. The lungs, in their connexion with the whole pulmonary circulation, are especially liable to be the seat of congestion. The heart, overtaxed, fails, for a time at least, to propel the blood through the distal pulmonary vessels, as it also fails to force the blood through the more distal systemic veins

\* Physiological Researches, 1851, repub. from Phil. Trans.

† See Med.-Chir. Trans., vol. vii., H. Earle; also, Human Physiology, Dunglison, 7th edit., vol. ii. p. 238.

leading to the surface of the body; the pulmonary veins become engorged with blood, stagnant, or nearly so. By-and-bye, the heart arouses, as it were, from its lethargy, and makes an effort to restore the systemic circulation, and to clear the pulmonary veins of their superfluous blood. This is reaction, attended with a glow of returning warmth and colour; and, simultaneously, determination of blood through the lungs. Reaction does not precede the determination of blood, and if it advance only so far as to restore the average force and frequency of pulse peculiar to the individual, such healthy reaction cannot be called fever; and if it proceed beyond this standard, and the determination of blood become persistent—in fact, inflammatory—even then inflammatory fever arises simultaneously with inflammation, and does not precede it. Then, as in other inflammations, the development of the fever follows the local determination of blood.

CAUSES; *External and Internal,—Exciting and Predisposing.*

The *External* causes of inflammation are manifold, but they may all be included under four heads. (1) Mechanical injury or irritation; as wounds, fractures, dislocations; or foreign bodies, introduced into the organism, as grit, portions of clothing, a splinter of wood, a bullet, and parasites, animal and vegetable; (2) Heat and Cold; (3) Chemical agents which decompose or kill living animal matter, as strong acids, caustic alkalies, chloride of zinc, and other escharotics; (4) Vital irritants, or animal and vegetable poisonous matters, and some mineral poisons; as the venom of noxious animals and plants, cantharides, mustard, capsicum, essential oils, arsenic, etc.

*Internal* causes may be either exciting and immediate, or predisposing, in their operation.

*Exciting* internal causes comprise, the blood, textures, and excretions, of the body, severally, under peculiar circumstances; and morbid products, organized and unorganized.

Blood extravasated and decomposing is a foreign body. So also are the various textures, when dying or dead; in the form of slough of the soft tissues, sequestrum of bone. The various excretions; as urine, fæces, bile, are irritants to the organs which naturally contain them, if such matters be in a state of decomposition; or if, being themselves healthy, they are extravasated; as urine into the scrotum, feculent matter into the peritoneum. These excretions are peculiarly obnoxious to cellular texture and serous membrane. Lastly, morbid products are apt to excite inflammation. Of deposits, softened tubercle does so in the lungs and other parts; of growths, cancer especially has this effect, the ichorous discharge more particularly being irritating. Calculi are familiar examples of unorganized products exciting inflammation in organs where they occur. For example, a stone in the kidneys provokes nephritis, in the bladder, cystitis.

*Predisposing* internal causes are those conditions which may constitute inflammation, only in a lesser degree; or short of, though bordering on inflammation. But the predisposition differs according to the nature of the cause which excites inflammation. Thus, an excited state of the vascular system favours the production of inflammation from local irritation; whereas, a depressed state of the vascular system favours the development of inflammation from exposure to cold.

It is not easy to refer an inflammatory predisposition to any one element of inflammation; but an approach to certain illustrations of their

respective influences is exhibited by the inflammation of different parts, wherein one or other of these elements predominate.

Thus, tissues whose reproductive power is greatest, and which are commonly, also, most vascular, are prone to inflammation; as for example, the skin compared with fibrous or tendinous structures. So also, tissues whose productive power is temporarily exalted, are ready for inflammation; as during the growth of the body in childhood and youth. The more vascular organs are similarly inclined; the lungs, for example, as compared with most other organs. The condition of the blood is specially influential; rheumatic and gouty inflammations are ever impending when an excess of lactic, or of lithic acid respectively is in circulation. Thence the predisposing influence of constitutional conditions generally, most of which are blood diseases manifested by various local inflammations, and ever ready to recur—as secondary syphilitic diseases of the skin and other parts, scrofulous affections of the bones, skin, and other textures. Other blood conditions predispose, as unquestionably, to local inflammations; but they require for their development the co-operation of external exciting causes, in each case peculiar, relatively to the special condition of blood, which is thereby brought into action. All the infectious and eruptive fevers are of this kind. [P. p. 310 et seq.]

Predisposition through the influence of the nervous system is evoked by nerve injuries, the operation of which in producing peripheral inflammation is thus generalized by Simon: "A part deprived of sensibility becomes specially incapable of protecting itself against mechanical and chemical irritants, and accordingly inflames—*e.g.*, the urinary bladder, subject to the action of retained urine, in paralysis. A part injured in respect of its innervation, is likely to suffer some circulatory disorder, with corresponding disturbance of natural temperature, and proneness to inflammation."

The co-operation of all these elements will render the predisposition complete, and almost give rise to inflammation. Thus, the functional activity of any organ, implying the concurrence of all the conditions essential to nutrition, in excess; such activity is accompanied with a proportionate proclivity to inflammation—as in the mammary glands, after parturition when lactation commences, and during its continuance, or the ovaries at the period of menstruation.

The operation of inflammation itself, as an internal cause, is both local and constitutional.

*Locally*, inflammation operates by extension, continuously, in the texture or organ affected; contiguously, to parts adjoining; or, by transference (metastasis) to a part remote from that originally affected, the inflammation then subsiding.

*Continuous* extension is witnessed in the progress of inflammation along the skin or mucous membrane—as in erysipelas, and the sore throat of scarlet fever.

*Contiguous* extension is illustrated by ulceration of the articular cartilages of any joint, consequent on caries of the adjoining head of bone, or on synovitis. Thus also osteitis supervenes on periostitis; cellulitis on inflammation of the skin, and conversely. Taking internal organs, from the head downwards: meningitis is succeeded by cerebritis; scrofulous and purulent ophthalmia, by inflammation of the cornea and deeper textures of the eye; laryngitis, by inflammation of the subcellular texture and œdema glottidis; gastritis, enteritis, cystitis, and metritis, respectively, may extend to the peritoneum, giving rise to peritonitis.

The *transference* of inflammation is exemplified by orchitis supervening on the sudden suppression of gonorrhœa.

Such then is the general operation of Inflammation locally ; constitutionally, its operation as an internal cause, was traced in the origin and development or the pathology of inflammatory fever.

**COURSE and TERMINATIONS.**—Inflammation may proceed to either of four Terminations ; Resolution, or disappearance ; Effusion, or lymph-production ; Suppuration, or as pus-formation ; Ulceration and Gangrene, or death of texture. Excepting the first of these terminations, that of resolution or simply cessation of inflammation, the line of demarcation between each of the remaining three modes of termination, is indistinct, and they are commonly more or less combined. A more definite line of distinction may be drawn between them, by regarding the course of inflammation in reference to its two principal constituent elements ; increased productiveness, and increased destruction, of texture. According as one or other of these predominates, so may we associate therewith the remaining terminations of inflammation respectively ; as effusion, and suppuration ; ulceration and gangrene.

1. *Resolution.*—Inflammation may subside and terminate without any permanent structural result. The redness fades away, the part recovers its healthy temperature, slight swelling if perceptible subsides, and exalted sensibility or pain ceases ; while any inflammatory fever passes off. This is resolution ; a termination of inflammation by the concurrent cessation of all the elements of this process ; and consequently, the cessation of its local and constitutional manifestations.

2. *Productiveness* may predominate ; then, Inflammation proceeds to Effusion, or, perhaps, Suppuration ; an increase of new material in the part, beyond the small proportion which necessarily attends inflammation. Liquor sanguinis appears, consisting of coagulable lymph and serum. In the latter constituent, the proportion of albumen and of salts is increased ; but of these there is a larger proportion of chloride of sodium and phosphates than in the blood.

Three conditions of lymph may be distinguished by tolerably well marked structural characters : the fibrinous and corpuscular of Paget, and a transition condition, consisting of both fibrils (filaments) and cells, the latter predominating. Similar susceptibilities of organization represent the varieties noticed by Dr. C. J. B. Williams, as the euplastic, aplastic, and cacoplastic. They differ also in point of vascularity, in the course of their development.

With these typical conditions of structure are associated tolerably definite physical properties : Fibrinous or Euplastic lymph—transparent, nearly colourless, and tenacious. Corpuscular or Aplastic lymph—opaque, yellow, diffuent. Transition condition or Cacoplastic lymph—opakish, yellowish, and less tenacious than the euplastic type. These characters are more clearly contrasted when placed in juxtaposition.

	Ex. False membranes.	Ex. Cirrhosis.	Ex. Pus.

The qualities of lymph are certainly most obvious when it is effused from simple membranes, as the serous—for instance, pleuritic effusions; while the more complex structure of skin and mucous membranes retard its separation, and modify its properties by the admixture of their own secretions. Hence the varied products of skin diseases, and those discharged from the gastro-intestinal canal, the urinary and pulmonary passages. Nevertheless, the peculiarities I have mentioned are fully confirmed by the observations of Mr. Paget, who carefully examined the materials exuded in thirty cases of blister from cantharides.

It will be desirable first to describe, more particularly, the elementary products of Effusion, including Suppuration; and then, their apparent source and mode of production, or the pathology of Effusion.

*Effusion—Products of Inflammation.*—(1) Coagulable lymph is more or less tenacious and at first transparent, but it acquires a slightly opaque yellow colour. It is produced in the form of minute villi. This appearance is best seen on free surfaces which are least subject to motion or pressure; as between convolutions of the intestines in peritonitis; between the lobes of the lungs in pleurisy; and about the base of the heart in pericarditis. But wherever serous surfaces are in contact and play upon each other, the ductile lymph is drawn into threads or plastered into films; as on free portions of the pericardium and pleura, and on the parietal aspect of the intestines.

Coagulation having taken place, coagulated lymph is somewhat solid, though still retaining its tenacity and opakish yellow colour. Its organization, in this its simplest condition of structure, is that of fine filaments, interwoven in various directions; as in the buffy coat of blood.

FIG. 1. \*

These filaments are formed apparently by the linear union of molecules, are homogeneous, and from  $\frac{1}{14000}$  to  $\frac{1}{10000}$  of an inch in diameter.

(2) *Cells* or corpuscles form in coagulable lymph, and are found interspersed among the molecular formed filaments, in coagulated lymph. These cells contain each from three to eight granules, the diameter of which equals that of the filaments. The cells themselves range in size from  $\frac{1}{1300}$  to  $\frac{1}{1000}$  of an inch. (See Fig. 1.) They have been named plastic by Dr. Bennett, because occurring so often in plastic lymph; and also named

\* Molecular fibres and plastic corpuscles, in simple exudation on a serous surface. Above are corpuscles after the action of acetic acid. 250 diam. (Bennett.)

pyoid by Lebert, from their general resemblance to pus corpuscles. But neither water nor acetic acid much affect these plastic cells.

Cells of this kind undergo development. By elongation, they assume an oat-shape; prolonged yet further in opposite directions, they are attenuated into filaments,—forming fibre-cells. Thence is produced *fibro-cellular*, or *connective*, tissue,—generally, the highest state of organization of inflammatory effusion. (Fig. 2.)

FIG. 2.

Blood-vessels are found in organized inflammatory lymph, and possibly in coagulated lymph, but they do not appear to be formed in it; they project into the new tissue from the structure on, or in, which it is placed. The vessels are formed by the same process of sprouting, coalescence, and construction of loops, as in granulations. Lymphatics were discovered by Schroeder Van der Kolk\* in false membranes. Nerves have been twice seen by Virchow† in adhesions; one of the pleura, the other of the peritoneum—between the liver and diaphragm.

*False Membranes* are formed on the inner or free surface of serous, and of mucous membranes; as in pleurisy, pericarditis, and peritonitis; in croup, and dysentery. Such membranes consist of inflammatory-lymph, which has undergone more or less development; and on serous surfaces, it may reach the state of organization just described, that of fibro-cellular tissue, supplied perhaps abundantly with blood-vessels.

The physical characters of false membranes vary according to their more or less high degree of organization and vascularity; the membrane formed is either pliant and yielding, or tough and unyielding.

Adhesion is apt to take place when the opposed surfaces of a serous cavity lined with inflammatory lymph, meet together. Similar adhesion may take place in wounds, or under other circumstances. Any such result of inflammatory lymph-effusion is sometimes referred to *adhesive inflammation*.

Other and more highly-developed tissues are reproduced. Many such results of inflammatory lymph-production are adduced by Paget.

\* Spec. Anat. Path. de Vasis novis Pseudo-membranarum, 1842.

† Würzburg. Verhandlungen, i. 144.

Adipose tissue may be formed, if not directly from inflammatory lymph, yet in the fibro-cellular tissue of completely organized adhesions. Elastic tissue is sometimes abundantly formed in the adhesions developed from inflammatory lymph, and particularly in those of the pleura. Epithelium covers the surfaces of well-formed adhesions. Fibrous tissue is produced from the development of inflammatory lymph, interstitially deposited in any fibrous tissue; as in ligaments, capsules of joints, &c. Bone is often formed, either as a late transformation of inflammatory lymph, which had become organized into perfect fibrous tissue—*e.g.*, osseous plates in false membranes of the pleura, and in those of the pericardium, which plates are not true bone; or new bone appears in the form of ossific deposits, connected with inflamed bone or periosteum. Cartilage is possibly formed in chronic rheumatic arthritis.\* This new cartilage is prone to ossify.

Lymph-effusion may undergo *absorption*; or if persistent, its operation may be either destructive, or reparative and constructive, and accordingly, unfavourable or favourable to the function of the organ or texture affected.

*Destructive* consequences of lymph-effusion are illustrated by many organs. The heart may be shackled by tags of false membrane, which continually restraining the action of this organ, at length induces its hypertrophy; a compensatory provision of increased structure for extra contractile power. Or the heart may undergo compression by great thickening of the cardiac reflexion of the pericardium, in consequence of the interstitial deposition of lymph therein, and thence the organ becomes atrophied. The lungs may suffer in like manner, either way. Peritonitis is apt to agglutinate the abdominal viscera into one mass. Within the substance of parenchymatous organs, contractile lymph being deposited, they become stuffed, consolidated, and sometimes atrophied and granulated. Such are old hepatized lungs, cirrhotic liver, and granular kidneys. Strictures are liable to form around canals; as the œsophagus, rectum, and urethra, narrowing or closing them and proportionably interfering with the functions of these passages. Eventually displacements of moveable viscera are wrought by the slow contraction of lymph-deposit, overcoming the struggle of function to recover the right adjustment of parts.

Analogous mischief may happen to the mechanism of the limbs; joints become stiffened by firm fibrous ankyloses, the tendons are bound in their sheaths, and the fasciæ agglutinated, in chronic rheumatism.

This fettered condition of organs, their consolidation and atrophy, obstruction, and displacements, are the principal destructive results of lymph-effusion.

On the other hand, its operation is not unfrequently reparative, to reinstate an old function, or constructive, to fulfil a new and useful purpose.

The *reparative* power of adhesive inflammation is manifested by the healing of incised wounds in those cases where the effusion of lymph is induced by inflammatory hyperæmia. The repair of simple fracture and of simple dislocation, when reduced, is an analogous process, and commenced probably by inflammatory hyperæmia consequent on the

\* Trans. Path. Soc. Lond., vol. iii. 1851. By W. Adams.

injury. So, also, wounded arteries are permanently closed by adhesion of an inflammatory character in some cases; and the healing of ligatured arteries is certainly effected by adhesive inflammation, which seals the divided coats of the vessel above and below the line of ligature. Penetrating wounds of the thorax and abdomen, implicating the viscera, afford ample and varied evidence of the reparative power of adhesive inflammation. Wounds of the lung are healed by adhesion of the pulmonary pleura consequent on inflammation. Wounds of the abdominal viscera are healed in like manner wherever the peritoneal investment extends; and the visceral reflexion of the peritoneum is very apt to adhere to the parietal reflexion of this membrane opposite the external wound. These results are explained in describing the healing of wounds of the abdomen and thorax respectively. In certain cases the peritoneum is purposely injured by the surgeon, so as to establish adhesive inflammation. This constitutes the radical cure of hydrocele and that of hernia; the former being accomplished by a stimulating injection; the latter by long-continued pressure with a truss; or the radical cure of hernia may be accomplished on the same principle by the successful operation recently introduced by Mr. Wood. Lastly, among the most familiar examples of beneficial adhesive inflammation, I may mention the well-known fact that foreign bodies, long imbedded in the living tissues, thus become enclosed in organized lymph, and their presence rendered comparatively harmless. An encysted foreign body is quiescent.

Reviewing these and similar results, there appears to be sufficient reason to justify Hunter's view of the use or purpose intended by adhesive inflammation. "It may be looked upon as the effect of wise counsels, the constitution being so formed as to take spontaneously all the precautions necessary for its defence; for in most cases we evidently see that adhesive inflammation answers wise purposes."

In conformity with this design, we observe inflammatory adhesion preventing suppuration, or confining its extent—in the pleura, in the peritoneum, occasionally; in the synovial capsules, and determining the boundary of an ordinary abscess; beyond which circumscribed limit, in any case, the pus formed cannot pass. Then, again, the same process prepares the way for the discharge of pus, without infiltration of the textures during its passage or escape into any natural cavity through which it may traverse. Any collection of matter having become circumscribed—as an abscess—by the deposition of inflammatory lymph, is gradually conducted through the surrounding textures at their most yielding point; the pathway having been previously paved securely for this purpose by their adhesion. The pus is still watchfully circumscribed during its passage, until at length the contents of the abscess are discharged. An abscess is thus advantageously opened by Nature. Absorption makes the channel, and in the direction of least resistance; but adhesion makes its banks secure. With this precaution a collection of matter is safely conveyed from a great depth in the body, and by an otherwise dangerous route. Witness the evacuation of pus from the pleura (in empyema), through a large and pendulous mamma. Adhesions of other serous surfaces favour the escape of matter. When a student, I once saw an abscess of the liver which pointed and threatened to burst externally, but which eventually relieved itself by perforating the diaphragm and right lung successively, a continuous expectoration of pus

being provided for by adhesion of the pleura where perforation had taken place. Sometimes, by a similar provision, an abscess of the liver discharges itself externally, or into the stomach, the duodenum, or the colon. An abscess of the kidney will also thus communicate with the colon; and an abscess in the right iliac fossa will be emptied into the colon, cæcum, or bladder.

These are instances of a new mechanism being constructed for some new, but perchance temporarily useful purpose, which is perhaps less frequently the intention of reparative inflammation than that of permanently restoring some lost part, and of thereby reinstating a former function.

(3) *Exudation corpuscles* are round or irregular little masses, having a dark and mulberry looking appearance, under the microscope. Their size is about  $\frac{1}{1000}$  to  $\frac{1}{750}$  of an inch in diameter. They consist of granules aggregated together, and sometimes enclosed in a cell-membrane; hence they are named also

FIG. 3.\*

compound granular corpuscles. (Fig. 3.) Within each of these corpuscles is seen a round transparent nucleus, varying in size from  $\frac{1}{3000}$  to  $\frac{1}{3000}$  of an inch in diameter. The granules vary from  $\frac{1}{12000}$  to  $\frac{1}{8000}$  of an inch. They are fatty. Acetic acid does not affect the cells or masses; but they dissolve immediately in ether, and disintegrate under the influence of potash or ammonia.

(4) *Pus* is a fluid having peculiar physical characters; an opake greenish-yellow colour, diffuent or creamy consistence, faint odour, and an average specific gravity of 1030, but varying considerably, from 1020 to 1040. All the characters of healthy pus differ considerably in the many diseased states of this product.

FIG. 4.†

This fluid consists of a serum in which are suspended an innumerable multitude of corpuscles. (Fig. 4.) They are spherical, somewhat granular-looking cells, from  $\frac{1}{200}$  to  $\frac{1}{300}$  of a line in diameter; and consisting of a cell-membrane, enclosing granular or molecular matter, and a nucleus situated, generally, on the (interior of the) cell wall and adherent.

It varies in size from  $\frac{1}{800}$  to  $\frac{1}{400}$  of a line across, and consists of two, three, or four granules aggregated together. These secondary nuclei are round, oval, sometimes elliptical. The whole cell,—its membrane, and contained molecular matter and compound nucleus, are albuminous. Water distends these corpuscles, and acetic acid dissolves the molecular matter, perhaps also the cell-membrane, and by loosening or breaking up the nucleus, displays its compound structure. (See Fig. 4, the five transparent cells.)

Pus has been analyzed by Güterbock, Valentin, Golding Bird, Wood, Von Bibra, and Wright, with unsatisfactory results.‡ I take the following particulars from the most recent work§ of authority on this subject.

\* Granular cells and masses from cerebral softening. (Bennett.)

† Pus-corpuscles, as seen in healthy pus; the fine transparent cells are as seen after the action of acetic acid. (Bennett.)

‡ See Pathological Chemistry. 1853. By Becquerel and Rodier. Translated by S. T. Speer, M.D. 1857. P. 529.

§ Chemistry in its Relations to Physiology and Medicine. G. E. Day, M.D. 1860. P. 221.

Pus-serum is a clear, colourless, or very faintly yellow fluid, having a weak alkaline reaction, and coagulating by heat into a dense white mass. Albumen is its chief constituent, in proportion from 1.2 to 3.7%. Fatty matter is extracted by ether, and it consists of olein, margarin, oleic and margaric acids, and cholesterin. These fatty matters vary from 2 to 6% of the whole fluid, of which proportion, cholesterin alone often reaches to 1%. Mucin, pyin, casein, chondrin, gluten, and leucine, are occasional constituents. The solid constituents of this serum range from 14 to 16%, of which from 5 to 6% are mineral, and the soluble salts are to the insoluble as 8 to 1. Of the former, chloride of sodium is most abundant, being three times more so than in the serum of blood. The soluble phosphates range from 3 to 10%. The insoluble salts are phosphates of lime and magnesia, with a little sulphate of lime and peroxide of iron. Certain incidental matters may be present in pus, as in any other exudation; namely, bile-pigment, the resinous acids of the bile, urea and sugar.

Pus is seldom found pure, but associated with various ingredients, the débris of surrounding textures, and mixed with secretions. Healthy or laudable pus may thus become serous, mucous, sanguineous, strumous, cancerous, &c. Or pus may be specific, as the syphilitic pus, vaccine matter, pus of porrigi, of glanders, &c.

The *formation* of exudation and pus corpuscles is, probably, as follows. Granules aggregate and constitute a compound granular mass. An investing cell-membrane may gather around such a mass, as a nucleus. Both these are forms of the exudation-corpuscles. Partial liquefaction of the peripheral granular matter of a cell-enclosed mass, may give rise to a pus-cell, with its compound granular nucleus. The chemical metamorphosis of cell-contents, or the substitution of albuminoid for fatty granules, is not understood. But the structural relation of pus-cells to exudation corpuscles, would seem to be a degenerative transformation. Several such transformative conditions of exudation corpuscles are represented in Fig. 3. Pus-cells are also structurally related, in some way, to those of mucus and chyle; and the whole series of cells—including exudation corpuscles—would seem to have a family relationship to the pale corpuscles of the blood; as being rudimentary states of these cells by arrests of their development.

The products of Inflammation are usually found associated; but one or other so far predominates, in different textures or organs, as to give its own structural character to the deposit; in cellular texture and parenchymatous organs, as the lungs, the product is chiefly granular matter and exudation corpuscles; in or on mucous membranes, chiefly pus; on serous membranes, chiefly coagulable lymph.

*Pathology of Effusion and of Suppuration.*—Analogy would lead us to expect a general resemblance between the processes of healthy nutrition and inflammatory effusion;—that the composition and vital condition of the blood will predispose to the formation of certain products; and that this process is affected by the degree of inflammatory hyperæmia, and by the force of the general circulation; that it is regulated by the nervous system; and is completed by the secretory or the formative power of the inflamed structure.

How far does all this anticipation accord with known facts?

First, as to the condition of the blood, in its relation to inflammatory effusion. Serum exudes from the engorged vessels, and fibrin therefore,

may also escape in a fluid state. But inflammatory blood superabounds with fibrin, and consequently this state will tend to deposit it more freely. The liquor sanguinis effused, will be, for the most part, fluid fibrin; and such is the typical character of coagulable lymph, which represents the first product of inflammation, before the formation of filaments, or of exudation, or pus-corpuscles. It is that which appears in the first instance on blistered surfaces, as demonstrated by Mr. Paget's observations.

The quantity of liquor sanguinis, and therefore of fibrin, effused, is further regulated by the degree of hyperæmia, aided by the force of the general circulation.

Virchow denies this explanation of fibrin-production. He argues\* that nobody has ever been able to prove the affirmative experimentally; that "nobody has ever been able, by producing a mere change in the force of the current of the blood, to induce the fibrin to transude directly, as it is wont to do in certain inflammatory processes; for this, some irritation is always required." I shall presently recur to the latter clause in this paragraph; but the want of experimental proof that fibrin is produced in an inflamed part, by the force of the blood's current, is, I think, compensated by familiar observations quite as conclusive as any experiments. When the pulse is strong and hard, the blood flows forcibly through unyielding vessels, and tells on an inflamed part; then fibrin is produced abundantly in that part: when again the pulse is rapid rather than strong, and compressible, the blood is misdirected; then less fibrin is found in the part inflamed. The former condition is illustrated by common phlegmonous inflammation, with much fibrin; the latter, by erysipelas, with much serum. This large proportion of fibrin, or of serum, does not, it is true, necessarily accompany only those states of the local and general circulation to which I have referred. The same results may possibly proceed from, and denote an excess of fibrin, or of serum, in the blood; the presence of the blood's circulation in an inflamed part may not be the only cause of a serous or fibrinous effusion: but whenever the circulation is active and tense, then there is a tendency to the effusion of fibrin; whenever the circulation is feeble and lax, then a tendency to the effusion of serum. The inference obviously suggested by this invariable sequence is, that a mere change in the force of the blood's current is a cause of fibrinous effusion. It is recognised as such in practice. Phlegmon and erysipelas are regarded as representing almost opposite conditions of the circulation.

Beyond these sources of lymph-effusion, it is possible that the character of the deposit may be influenced by the nervous system; but the share of its influence, if any, must be determined by future inquiry.

Lastly, the structure in which inflammation takes place, may itself exercise some power, either by selecting the fibrin from the blood, thereby inducing its effusion, or by producing it in the inflamed part through metamorphosis of the material effused. In other words, an inflamed structure may possess either a secretory, or a formative power.

Virchow adheres to the latter view, and maintains by experimental observations, that irritation induces the effusion of a fibrinogenous substance, which can be converted into fibrin. In proof of the self-sufficiency of irritation, Virchow adduces the operation of a blister; that

\* Cellular Pathology, p. 163.

firstly, serum only is yielded, but if the irritation be more violent, a fluid which coagulates. The general doctrine advanced is thus stated: "A patient who produces at a certain point a large quantity of fibrin-forming substance, much of it passes from that point into the lymph, and finally into the blood. The exudation may therefore in such cases be regarded as the surplus of the fibrin formed *in loco*, for the removal of which the lymphatic circulation did not suffice. As long as the current of lymph does suffice, all the foreign matters which are formed in the irritated part are conveyed into the blood; but, as soon as the local production becomes excessive, the products accumulate, and in addition to the hyperinosis, a local accumulation of fibrinous exudation will also take place."

More consistent with known facts is the operation of a secretory power, by which structures select this or that constituent of the blood as it passes through them, and by which the effusion of that particular constituent is determined. An approach to the proof of this theory is, I conceive, the behaviour of the same blood in different textures. Blood, having the same composition and properties, deposits in one inflamed part much fibrin; in another, rather albumen; in a third, more fatty matter. In pleuro-pneumonia, for example, fibrin and a large proportion of serum are effused from the inner surface of the pleura; an albuminous matter is deposited in the lung-parenchyma; and pus, in which fat abounds, is more readily secreted from the (bronchial) mucous membrane. These products are known ingredients of the same blood, flowing alike to each of the three structures mentioned, and yet they severally receive a different kind of deposit. The inference is, that the particular deposit is selected or secreted by the particular kind of texture. How far this secretory power is a vital property; how far it results from the physical construction of the texture, is an open question. Assuredly the physical consistence and permeability of a part will very much affect its capability of receiving this or that kind of effusion.

Probably all the causes of effusion co-operate. The "composition and properties of the blood," the "hydraulic state of the circulation—both local and general," the secretory power of the "structure," and perhaps "nervous influence," are each engaged; and sometimes serum is the prevailing product, sometimes fibrin, as I have explained. This latter soon coagulates, and the effusion, at first fluid, assumes the physical character of a mixed product—partly solid, partly fluid, varying in this respect as either fibrin or serum prevails.

Pus is a new product; but its evolution appears to be governed by conditions analogous to those which regulate the formation of other inflammatory products, and those of nutrition in general. "Secretory power" is in operation, regulated probably by "nervous agency," and determined by the "condition of the blood;" possibly also by the "flow of that blood to the part."

Pus has been termed a secretion; and its constant production in connexion with certain textures, rather than others, although the blood be the same, plainly indicates that such parts possess and exercise some secretory power.

The readiness with which mucous membranes suppurate is well known. Bronchitis, enteritis, and cystitis are prone to induce purulent sputa, fæces, and urine, respectively; indeed, pus has been found on a bougie five minutes only after it was introduced into the urethra. Other

textures are far less prone to suppurate. An incision through the skin and subcutaneous cellular tissue probably unites by adhesion, without any suppuration, or pus is not produced for two or three days.

Observations such as these tend to establish the theory, first advanced by Simpson,\* that pus is a secretion. Certainly it is as much so as cuticle and all other tissues. They are evolved from a blastema, effused from neighbouring vessels; and pus is also the product of a blastema, but which is effused by inflammatory hyperæmia. The doctrine of pus-secretion was likewise suggested by De Haen; and a few years afterwards, Dr. Morgan† fully discussed the whole question. Brugmann‡ followed with a similar view; and at length Hunter§ adopted and supported this secretion theory, without, however, having first suggested it, as is sometimes asserted.

The pus-forming power of textures is probably regulated, like other secretory power, by the nervous system. In paraplegia, cystitis usually ensues, and this paralytic cystitis produces purulent urine in a more marked degree than cystitis arising from other causes. Injury of the fifth pair of nerves is followed by suppuration of those parts which they supply. Such cases show the effect of intercepting the nervous influence to a part; but the nervous system exhibits its influence by inflammation and suppuration of a part through sympathy with some irritation in another and perhaps distant part. Mr. Paget refers to a specimen|| where extensive deposits of lymph and pus were found in the testicle of a man whose urethra contained a portion of calculus impacted after lithotomy. Analogous cases are on record. The influence of mental emotion in producing inflammation with speedy suppuration is manifested by the following case,¶ and of which there are similar ones. A lady was watching her little child at play, and she saw a heavy window-sash fall upon its hand, cutting off three of its fingers. In a short time the mother also had inflammation of the corresponding three fingers of her own hand, and in twenty-four hours pus was evacuated by incision.

Pus-production is determined very much by the condition of the blood. One would suppose so, judging from the analogy between pus-secretion and other efforts of the secretory power. Certain experiments made by Mr. Paget supply apposite illustrations. They show that the same tissue, inflamed by the same stimulus, and as near as possible in the same degree of inflammation, yields, in different persons, and in whom therefore the blood may be considered dissimilar, different forms of lymph. The inference is obvious, that blood-conditions determine the kind of product which shall be formed, or, as we may say, secreted. I have already noticed this doctrine and these experiments. Blisters raised by cantharides in thirty patients gave sometimes a fibrinous, sometimes a purulent product. It was found that in cases of purely local disease, in patients otherwise sound, the lymph formed an almost unmixed coagulum, in which, when the fluid was pressed out, the fibrin was firm, elastic, and apparently filamentous. Whereas, in cases at the opposite end of the scale, such as those of advanced phthisis, a minimum of fibrin was con-

¶ *Pathology and Treatment of Hysteria*, Carter, 1853, p. 24.

sealed by the crowds of corpuscles imbedded in it. Mr. Paget therefore concludes that the highest health is marked by an exudation containing the most perfect and unmixed fibrin; the lowest, by the most abundant formation of corpuscles, and their nearest approach, even in their healthy state, to the characters of pus-cells.

Has continued determination of blood any influence in producing pus? It has been alleged, that, "such a result is most likely to ensue in complex and highly vascular structures, where the effused matter is retained in intimate contact with the blood-vessels; hence intensity and continuance of inflammation in the true skin, cellular textures, glands, and most parenchymatous organs, pretty surely lead to suppuration."\* And in explanation of this process, it is suggested by the same authority, that, as under the exaggerated "influence of the red-corpuscles (which convey oxygen) on the liquor sanguinis, more of its protein passes into the state of solid deutoxide,—a material fitted for organization and reparation; so we may infer that the excessive degree or continuance of the same action may overdo this change, give chemical properties an ascendancy over the vital powers, and by turning the most recently-formed solid into a fluid tritoxide, may effect a work of separation and destruction, involving the blood in the obstructed vessels, and extending to the albuminous matter of the containing texture."

This chemical theory needs no further refutation than the now acknowledged fact, that protein itself is a chemical myth, having no existence, and of course therefore incapable of forming a deutoxide, and then a tritoxide. But what influence does persistent determination of blood exercise, under the circumstances of pus-formation, in complex and highly vascular structures? If an incision be made when pus is about forming in a large boil, an abundance of solid lymph is seen agglutinating the cellular texture. Pressing as this does upon the vessels which it encompasses, they become, at least partially, occluded. Inflammation being far advanced, "obstruction" is now added to "persistent determination" of blood. And this obstruction, this solid lymph and agglutinated cellular texture, may extend for some distance, giving the external swelling a broad base. Around the periphery of the solid swelling blood plays freely, yet without pus forming there; whereas, in the centre, first appears a white spot of pus, far removed from the circumferential determination of blood. This afflux of blood goes on depositing fresh lymph, thus enlarging the swelling; while in the midst of the solid lymph and occluded vessels, more and more removed from all such external influence, suppuration proceeds. Persistent determination of blood, therefore, only prepares a structure for suppuration; suppuration itself is an independent process. Consequently, we are not surprised to discover pus in a texture where determination of blood cannot have availed much; as in the centre of a large fatty tumour, itself but ill provided with vessels for its own supply of blood; and the freest afflux of blood without suppuration, as in a gouty toe.

*Signs of Effusion, and of Suppuration.*—Inflammatory Effusion is attended with swelling, in consequence of the progressive accumulation of the products of effusion. The nature of this swelling may be recognised partly by considering the physical character of the products; liquor sanguinis presenting a swelling, at first fluid, but as coagulation ensues, it soon assumes the character of a mixed product—solid and fluid, varying

\* Principles of Medicine, C. J. B. Williams, M.D., 3d Edit., p. 364.

as either fibrin or serum prevails. The diagnosis of a chronic swelling of doubtful character, can be completed by puncturing its substance, and if necessary by further examination with the microscope of the very matter effused or the resulting products.

*Suppuration* is announced by a throbbing or pulsating pain, increased heat, redness and swelling. But proceeding as these signs do from increased determination of blood—a condition not essential to suppuration—they are not invariably present, or followed by suppuration; the inconstancy, in either respect, depending on the kind of texture in which inflammation takes place.

In any unyielding texture, inflammation is accompanied with a throbbing pain, without suppuration, necessarily, ensuing; toothache being a familiar example. In a loose parenchymatous texture, which more freely admits the afflux of blood, extensive suppuration may have supervened, without any previous throbbing; as in the cellular texture of the ischio-rectal fossa.

Conversely, with regard to increased swelling;—in loose cellular texture, considerable effusion and swelling may have taken place, without suppuration ensuing; while, in an unyielding texture, an abscess forms, without any previous increase of swelling.

The diagnostic value of these symptoms is perhaps fairly this; when suppuration does occur, in unyielding textures, it is invariably preceded by throbbing, with increased heat and redness; and, in yielding textures, by increased swelling. Otherwise these are not constant signs of approaching suppuration. Consequently, they are not absolutely trustworthy as premonitory symptoms.

But the physical properties of pus confer certain distinctive characters on any soft part in which it is formed. Just as the first effusion of lymph is recognised by a semi-solid swelling, arising from the products—fibrin and serum—into which that lymph has become resolved; so now another product,—fluid, but of creamy consistence, and slightly viscid, imparts a more elastic feel to the swelling. It is the sign of *diffused* suppuration, and this condition may continue, or a further change take place.

*Abscess.*—Lymph may become deposited so abundantly around the focus of suppuration, as to effectually circumscribe and imprison the pus. The textures, thus encompassed, die, disintegrate, dissolve, and are removed by absorption, leaving the pus, more or less pure, in their place. An abscess is formed. The circumferential lymph of this pus-containing cavity, assumes, somewhat, the structure and characters of mucous membrane, and acquires a secretory power. It becomes pus-forming, as well as pus-containing; it is a pyogenic membrane. And as it absorbs old pus, as well as secretes new matter, the abscess is gradually concocted or ripens.

The Signs are now those of abscess. The throbbing pain, heat, and redness, all the signs of previous active hyperæmia, are mitigated by the yielding resistance of pus as compared with that of partially solid lymph; unless the matter be confined under any unyielding-texture, such as a fascia, or within bone. But a fluid and fluctuating swelling is presented, rather than one having the solidity of coagulated lymph, or the greater elasticity of pus diffused.

Like any other structure, pyogenic membrane may lose its functional power; then, pus-secretion failing, while absorption continues and prevails, the abscess dwindles and gradually disappears; or, retaining its

power unimpaired, secretion and absorption are, perhaps, equally balanced, and the abscess remains stationary and becomes *chronic*; or, lastly, acquiring a higher degree of secretory power, pus accumulates, the pyogenic membrane itself grows proportionately, and the abscess enlarges. The pus-secreting sac or cyst, thin and smooth, is gradually transformed into a soft spongy membrane, slightly mammillated, and of a greyish or reddish brown colour, as seen after death. This sac is attached to the surrounding textures loosely or closely. They are detrued and absorbed under constant pressure by the expanding abscess, and thus the area or size of the fluctuating swelling increases.

At length—in a variable period, usually before the abscess becomes chronic—absorption of the pyogenic membrane itself begins, under the expansion of constant fluid-pressure. And, generally, in the direction of least resistance the abscess *points*; the circumferential tissues undergoing absorption more readily, or yielding more in that direction as the expanding force there gains advantage. On the side of the abscess opposite to this thinning portion, the pyogenic membrane, according to Macartney's observations, actually grows thicker, and contracts so as to exercise some degree of expulsive power. A prominent point appears, over which the skin assumes a dark livid tint, and the cuticle is shed in eccentric rings. Here fluctuation is most perceptible. Soon a small slough separates and pus escapes. Thus also in the case of mucous membrane, an aperture is formed; but serous membrane yields with a rent. Distension is relieved, and if the aperture be sufficiently free and dependent, or made so, the matter is discharged or drains away daily, coagulable lymph is effused instead, and forming granulations, it contracts towards the aperture, and gradually closes the cavity of the abscess. The residual abscess is now a healing *ulcer*, and the process of reparation is completed in a period varying from, perhaps, twenty-four hours to days, weeks, or months.

If contraction be incomplete, the sac of the abscess is brought together only here and there, leaving intervening pus-producing cavities; a *multilocular* abscess is formed. Or, the cavity contracts into a long narrow channel, lined with a perfect pyogenic membrane throughout its course, and having an obstinate indisposition to heal; a *fistula* is formed. It is convenient to distinguish a *sinus* by the absence of these characters.

The latter is said to be distinguished from the former, principally, by its having only one opening; a sinus being a long, narrow, suppurating canal, opening externally or internally, and having little disposition to heal. But either such canal is an incomplete fistula; as may be fistula in ano. The minute structure of the walls of these passages, the different appearances of their aperture or apertures, and the modes of their formation, are details, for the most part, of little practical importance, or pertain rather to special and regional pathology.

Sometimes the process, after evacuation, is unhealthy, and without any tendency to heal. The sac secretes a fetid sanious pus, induced probably by the admission of air or by some constitutional disorder affecting the pyogenic membrane, and the production of granulations is delayed. Or, at a later period, when the abscess is reduced to an ulcer, it, like ulcers arising otherwise, may exhibit an obstinate indisposition to heal. From constitutional causes, chiefly, this ulcer may become indolent, irritable, inflamed, or phagedænic.

The function of pus may be inferred from its relation to the process of healing by suppurative granulation, in a healthy ulcer or sore. The cells of pus are either degenerate or immature granulation-cells. If the former, pus represents the superficial portion of organized granulation-matter, which, having lived its time, passes off, just as the outermost epithelial cells are shed. If immature granulation-cells, pus represents the superfluous portion of organizable granulation-matter, which never reaches maturity. This is the more probable interpretation. Compare pus-cells—as unaffected by acetic acid—(fig. 4, cells to the left), with granulation-cells (fig. of granulation-structure, in this work), and their great similarity or identity will be obvious. As immature granulation-cells, pus ceases to be secreted when the granulations come to the level of the skin, for then, the ulcer being filled up, no more organizable material is needed. Suppuration may thus be associated with a restorative or reparative purpose; as in the closing of an abscess after evacuation of its contents, and in the healing of open wounds, compound fracture and dislocation.

The situations where abscess originates are regulated, it would seem, very much by the different kinds of texture. Rarely, if ever, is abscess formed in fibrous or cartilaginous tissues, nor within any serous membrane. The situations where abscess may be found, are very various. It may have extended from its seat of origin to another, and perhaps distant, locality.

Abscess by *translation*, as any such extension is termed, somewhat inaptnly, is favoured by various circumstances; by the difficulty with which pus produced in certain parts, finds its way to the surface; by the comparative facility with which it travels to other parts; by slow progress of the abscess, allowing opportunity for its extension; and by special circumstances conducing, which are peculiar to each case. Examples of such abscess occur chiefly in connexion with the spinal column. Taking them from above downwards; abscess arising from disease of the cervical vertebræ, may present directly forwards behind the pharynx; or it may extend behind the sterno-mastoid muscle to the side of the neck; or into the axilla, or the thorax; from the dorsal or lumbar vertebræ, abscess may present directly backwards, or forwards into the thorax or abdomen; or it may extend downwards—through the aortic opening in the diaphragm, in the case of dorsal abscess—and forwards, between the abdominal muscles, to some point in front of the abdomen; or to the external abdominal ring; or, guided, apparently, by the obturator vessels and nerve, to the obturator foramen, it points in the upper part of the thigh; or, within the sheath of the psoas muscle to the upper part of the thigh, more externally, it appears as *psoas abscess*;—or passing thence lower down, it may point in the popliteal space, the calf, or even as low down as the ankle; or extending, from its seat of origin, downwards, and inwards, into the pelvis; this abscess may point at the side of the vagina, rectum, or sacro-sciatic foramen; or escaping thence, burrow externally between the bone and gluteal muscles, thus presenting in the gluteal region. Abscess by translation is further illustrated, by extension from the seat of origin in the shoulder joint to the elbow; or from the hip to the knee. [P. p. 492.]

The Signs of any such abscess are; a fluid, fluctuating swelling, like that of an ordinary abscess; but its concomitant redness, heat, and pain, are absent. Some degree of inflammation may ensue, from the weight of pus on the most dependent part of the abscess, and pain also may be experienced, owing to pressure on nerves in the neighbourhood.

*Hectic Fever.*—The constitutional disturbance or hectic fever consequent on suppuration and abscess, is characteristic. Commencing at a variable period in the course of inflammation, the first symptoms are those of prostration with excitement. A sensation of chilliness or a shivering fit—rigors, announce the one, while the other—nervous excitement—is exhibited by restlessness and sleeplessness, the pulse also retaining its frequency, or rising in rapidity, although losing its force and hardness. The heat and flush of skin subside, a cold clammy sweat supervenes, the urine becomes pale, abundant, and deposits a pinkish sediment of lithates. The tongue loses its brown fur, is white and pasty with a bright scarlet tip; the appetite is very capricious, sometimes absent, with loathing of food and even vomiting; while profuse watery diarrhœa succeeds to the previous constipation. Progressive emaciation and trembling weakness bespeak the failure of nutrition; and the general course of the symptoms at length proclaims the victory of exhaustion.

Hitherto inflammatory fever has subsided uninterruptedly; but if the struggle be prolonged, it acquires an intermittent character,—exhaustion prevailing, yet with recurring efforts of excitement, particularly of the circulation, followed by increased secretions from the skin, kidneys, and bowels. Thus, towards evening, after a day of dread exhaustion and when the skin is pallid, a chill is felt; soon the pulse rises in force slightly, and in frequency to perhaps 100 or 130 beats per minute. Then the patient temporarily revives; the hollow cheeks are crowned with a tint of crimson hue, and the sunken eyes are lustrous; giving to youth and beauty a complexion and an expression which are not of this world. The palms of the hands and soles of the feet feel hot and dry. During the night or towards morning, this fitful fever abates with profuse perspiration, urgent liquid diarrhœa, and probably diuresis. Daylight is welcomed, but only with feelings of greater prostration.

Such is hectic fever. Intermittent, it recurs at various periods; frequently as a quotidian, sometimes as a tertian or quartan. Thus far resembling other intermittent fevers; hectic has diagnostic differences. It seldom recurs, as Dr. Thomson observed, at a period perfectly regular, for more than three or four paroxysms. Then recurring at irregular intervals, it may disappear entirely for ten or twelve days; unlike the course of ague. Moreover, the intermissions of hectic are not complete, the pulse still remaining above par, and very easily excited. It is rather a remittent fever. Hectic, therefore, may recur two or three times daily; and a very slight degree of emaciation, a pulse a little quicker than ordinary, with a slight increase of heat, particularly after meals, are sufficient to constitute incipient hectic. These are the earliest symptoms. Rigor is not necessarily the earliest, nor the most constant constitutional announcement of suppuration, and of approaching hectic. This symptom may be present without suppuration and consequent hectic, as the harbinger of an ague fit, or as arising during inflammation from exposure to cold; or from the mere introduction of a bougie into the urethra. On the other hand, hectic fever sometimes supervenes stealthily, without previous rigors.

*Pathology of Hectic.*—The causative relation of suppuration to hectic fever, would appear to be, not through purulent infection of the system, but through absorption of the disorganized textures, and thence proportionate to the progress of suppuration.

Purulent infection is irreconcilable with known facts. Pus often

exists in the body without hectic supervening—as, for example, in chronic diseases of the joints, and in psoas abscess. Probably, however, in such cases absorption is not very active. In other cases, pus is readily absorbed, yet without inducing hectic. A large bubo will sometimes subside in a few days without any symptoms of hectic, and every pus-secreting ulcer is liable to absorb its own secretion, and yet hectic is an unusual concomitant. Purulent absorption, therefore, is not a cause of hectic fever. On the other hand, I am not prepared to assert that hectic ever occurs without suppuration. Assuredly the quantity of pus formed is no measure of the degree of hectic which shall ensue; for after amputation, say, of a compound fracture, a much larger quantity of pus may form eventually, before convalescence, than had been secreted during the period prior to amputation, and yet the hectic shall subside.

Recovery follows the removal of the disorganized part. In some way, therefore, a causative relation exists between the disorganization of a part, and the supervention of hectic. It cannot be that the progressive destruction of nerves by suppuration, and the injury thereby continuously inflicted on the nervous system, gives rise to hectic, for the symptoms are not those of nervous irritation, and, moreover, they are intermittent, or at least remittent. This certainly looks as if some noxious matter was gradually absorbed and accumulated in the blood, until thrown off by a hectic paroxysm, again to reaccumulate. The matter in question is not pus, or if absorbed it does not infect: by exclusion we are led to infer that the morbid matter is probably the *débris* of the disorganized textures. Clinical observations and examinations of the blood in hectic are wanting to confirm this view; meanwhile it is a significant fact, that the urine deposits lithates during the decline of each hectic paroxysm.

This interpretation of hectic indicates the relationship existing between the progress of suppuration and itself.

If hectic arises from absorption of disorganized textures; then, it must increase with the progressive formation of pus: not that pus, in such case, itself infects, but because its formation necessarily implies the concurrent and corresponding absorption of the encompassing textures, and by thus poisoning the blood, induces hectic fever. Suppuration and hectic are, therefore, related indirectly, as cause and effect; and moreover, the quantity of pus accumulating or discharged, actually becomes a fair measure of the degree of hectic.

Certain acknowledged principles of preventive treatment admit of explanation by the theory I have advanced. Absorption of the textures is checked when the progressive accumulation of pus is prevented; hence, the importance of making an early, free, and dependent opening, for this equally allows any *débris* of the tissues to escape. Again, absorption of disorganized tissues is altogether prevented by removing them; hence, the necessity for amputation where their destruction is extensive and beyond hope of recovery to a healthy condition. Amputation under these circumstances is often followed by surprisingly beneficial results. As Hunter originally observed, a hectic pulse at one hundred and twenty has been known to sink to ninety in a few hours after removal of the hectic cause. Persons have been known to sleep soundly the first night afterwards who had not slept tolerably for several preceding weeks. Cold sweats have stopped immediately, as well as those called colliquative. Purging has immediately ceased, and the urine begun to drop its sediment.

All these facts and considerations harmonize with the theory, that hectic fever arises from absorption of disorganized tissues. Pus itself sometimes, apparently, enters the circulation, as pus; but this produces very different constitutional symptoms and results; those of *pyæmia*, followed by *secondary* abscesses. The circumstances under which purulent infection arises will be noticed, more particularly, in connexion with that subject. Respecting the symptoms, it may be here summarily stated, that they are still those of a blood-poison, and of a typhoid character, but the exhaustion induced is more speedy, and more overwhelming—more typhoid; and the poison is either not eliminated at all, or insufficient to allow of marked intermissions,—the fever is less intermittent, or more continued, than hectic.

(3.) *Destruction of texture*, as a result of inflammation, comprises mortification and ulceration. Mortification, or the death of a part, receives different names according to the partial and recoverable, or total and irrecoverable, loss of vitality in the part affected; the one condition being named *gangrene*, the other *sphacelus*. Both these terms refer to death of the soft textures, and when this takes place to a limited extent and is accompanied with ulcerative separation from the living textures, it is termed *slough*, and the process, a sloughing of the part; when bone is affected, mortification is called *necrosis*, and the dead portion, a *sequestrum*, and its separation, *exfoliation*. This latter term is sometimes restricted to the detachment of an external portion of bone, in the shape of a thin scale or plate.

*Ulceration* may be conveniently described first, as being in its nature introductory to mortification.

The phenomena of ulceration generally, are these:—A portion of integument having become inflamed, from any cause; after a few days a small piece separates and comes away, leaving a corresponding loss of substance—a chasm, from which a discharge, variable in kind and quantity, issues. Thus, then, the skin, or mucous membrane, with perhaps the subjacent cellular tissue, has undergone a “solution of continuity,” slowly, however, as contrasted with a wound, or other recent breach of texture, and an *ulcer* is formed. Its formation and extension constitute ulceration.

The pathological nature of this process has long been a disputed question. All the explanations advanced may be reduced to two heads.

Firstly.—That ulceration signifies molecular disintegration, liquefaction, and separation of the soft parts, thereby leaving a chasm.

Secondly.—That ulceration is an illustration of the process of absorption, the lymphatics and veins being jointly engaged, more especially the former.

Possibly, both modes of removing the disorganized textures co-operate in ulceration. [P. p. 512.]

Textures undergo certain changes of structure preparatory to their ulceration. The latter is essentially molecular disintegration; but, in so far as it proceeds from inflammation, degeneration of texture prepares the way for such disintegration. And the previous degeneration is generally fatty.

The proper discharge from an ulcer—the product of ulceration, not of a granulating sore—is *ichor*. It is a thin sanious fluid, colourless or slightly yellow, structureless, but mixed with exudation, pus, and blood, corpuscles, and with the *débris* of the ulcerating textures. Hence its variable appearance. Its essential chemical composition is unknown. Ichor cor-

rodes the living tissues, and is thus distinguished from pus, which it often resembles in appearance. Thus also it maintains and extends ulceration.

Ulceration, although itself a destructive process, is sometimes restorative or reparative, in virtue of its purpose. For example, by the pointing of an abscess and the natural formation of an opening for the escape of matter externally, or internally into some channel through which it can be safely discharged,—as through the bronchi, stomach, intestine, or bladder.

*Mortification* is only another mode in which any part of the body may die; a reciprocal relation subsisting between this process of destruction and ulceration. They differ in degree, but are one in kind. Ulceration may be exaggerated into mortification, and this may subside into that. Both are convertible by different gradations of the same process of destruction. Thus, now and then during ulceration, some temporary cause may accelerate the inflammation; a larger portion of tissue undergoes degeneration and dies, than can, conveniently, disappear as discharge, and a corresponding portion, therefore, of dead tissue becomes visible in the shape of slough; instead of having been removed imperceptibly by molecular disintegration and liquefaction, aided by the corrosive action of the ichorous secretion. Accordingly the ulcer presents a rim of slough, and from time to time, another and another, as the margin of the ulcer recedes and enlarges, either by sloughing or ulceration. Of course the sloughs will vary in their depth and extent, sometimes approaching the result of molecular disintegration, sometimes appearing as obviously portions of dead tissue, plainly showing the transition of ulceration to mortification. Small fragments of bone may be detached and cast off with the fluid from an ulcerating surface, and these, observes Mr. Paget, when they are not fragments of tissue detached by ulceration extending around them, are good examples of the transition that may be traced from ulceration to sloughing or gangrene of parts.

The conditions which constitute inflammation, if operating with sufficient duration, end either in ulceration or mortification. And indeed the very fact of pus—a product of inflammation—accumulating in any texture or organ, by progressive suppuration, necessarily implies the death and removal of the occupied portion. The determination and kind of blood, the kind of texture, and the nervous influence on the part, are the conditions referred to; but each or all of them are so modified as to have a tendency to death. The determination of blood may be more intense, or the kind of blood may be that which indicates the operation of some blood-poison, or at least a morbid condition of the blood, as in carbuncle and boil, phlegmonous erysipelas, sloughing bubo, and certain secondary syphilitic ulcerations, hospital gangrene, malignant pustule, malignant scarlatina, and small-pox. Unyielding textures are liable to gangrenous inflammation, owing apparently to strangulation of the capillary vessels, consequent on effusion which cannot be accommodated interstitially. Inflammation of any texture situated beneath one of this kind, as beneath a fascia or tendinous aponeurosis, has also a gangrenous tendency, and thus subpericranial inflammation is soon followed by gangrene and sloughing, exposing the scalp. But inflammation of a loose texture, if a comparatively avascular one, as the subcutaneous cellular tissue, is prone to sloughing, owing apparently to strangulation of the vessels, consequent on the ready accumulation of effusion—*e.g.*, in phlegmonous erysipelas. The influence of the nervous system is shown by the ten-

dency to sloughing from injury to the spine. Mortification of the ankle has thence followed within twenty-four hours. (Brodie.) Ulceration of a part may supervene on injury of the nerves leading thereto; a central penetrating ulcer of the cornea was thus formed in consequence of destruction of the trunk of the trigeminal nerve by the pressure of a tumour near the pons varolii. (Paget.) And in another case, under my own observation, in the Royal Free Hospital, a similar ulcer of the left cornea followed an injury to the posterior part of the left side of the head. There was also considerable injection of the conjunctival vessels, and mucous secretions. These symptoms ceased, and the ulcer healed subsequently, leaving a slight opacity in the centre of the cornea. Other illustrative cases are on record. [P. p. 566.]

The Signs of gangrenous inflammation are,—acute burning pain, instead of the throbbing of approaching suppuration. The redness deepens into purple, and thence to a livid hue, a change of colour due to stagnation of the blood in the dying part. The swelling, moreover, is peculiar, for here the textures are disintegrating and softening, macerated also by the effused fluid in which they are soaked. Hence a flabby softness is presented. Phlegmonous erysipelas, as it advances, well illustrates these signs of gangrenous inflammation.

Their diagnostic value is assured by their constancy and exclusiveness; they are never absent collectively in gangrene resulting from inflammation, nor present collectively in any other disease. Acute burning pain is, perhaps, the earliest or premonitory symptom.

From this condition of local disorganization the *constitutional* disorder at once commences. More insidious, its symptoms resemble those of pyæmia, although differing in degree. A wild, apprehensive look, with great restlessness, are conspicuous; the features and manner at length become more composed, and the face assumes a pallid hue. The skin over the whole body and the tunica conjunctivæ sometimes acquire a peculiar yellow colour. (Brodie.) Utter prostration of mind and of muscular power gradually supervenes, and a quivering subsultus tendinum. The pulse beats very feebly, rapidly, and irregularly, feeling like a rough wire drawn under the finger. The secretions are soon perverted; the skin, at first hot and dry, is now bathed with a cold, clammy sweat; the urine, fetid and scanty, may be suppressed; a brown, rough, dry tongue is accompanied with nausea and a putrid diarrhœa. As the powers of organic and of animal life fail, involuntary excito-motions predominate; spasms and convulsions shake the moribund body, while coma ends in death.

This represents the course of an extreme case of gangrenous inflammation; but, short of it, various degrees of the same constitutional disturbance occur in different cases, and it represents also the constitutional disturbance which proceeds from spreading gangrene.

But the gangrene may cease to spread. The reddish-brown tint of the skin in advance of the dead part becomes brighter and more circumscribed. Shortly, a white raised line of demarcation is seen in the living skin immediately adjoining the dead portion. Soon this line melts away into a groove by ulceration; extending deeper, it forms a fissure, and successively passing down through tissue after tissue at length converges, and completely detaches the whole of the dead part. While the living organism is thus separating itself from the slough, adhesive inflammation precedes the line or fissure of ulceration, and, corresponding to it in

length and depth, simultaneously seals the blood-vessels; so as to effectually exclude any further communication with the dead tissues, and prevent absorption of their *débris*. The typhoid type of fever passes off, and is exchanged for some degree of inflammatory fever, which accompanies the process of separation and detachment of slough.

The typhoid fever of gangrenous inflammation arises, apparently, like hectic fever, from absorption of the disintegrating and dying or dead textures.

This conclusion rests on two species of evidence.

Firstly, the fever arises, and invariably, when mortification has advanced to sphacelus,—*i.e.*, when dead tissues are present; and, moreover, when the veins, in some cases at least, are free to absorb.

Secondly, it begins to subside, and invariably, when sphacelus has ceased to spread,—*i.e.*, when the living organism is separating itself from the dead part, and when adhesive inflammation of the blood-vessels, corresponding to the line or fissure of separation, has intercepted any further communication through these vessels with the dead tissues. [P. p. 526.]

Mortification, itself a destructive process, is, like ulceration, occasionally restorative, or reparative, by virtue of its purpose. It is so in the loosening and evulsion of a foreign body by sloughing of the part wherein it is imbedded,—the natural process whereby a thorn in the flesh is extricated. The spontaneous cure of aneurism, by sloughing, is another example; with many others of similar character. [P. p. 803.]

TREATMENT OF INFLAMMATION, AND ITS CONSEQUENCES.—The earliest occasion for interference with inflammation is determined by considering its purpose with reference to the part affected. If it be reparation of some loss of structure, or the construction of some new and useful mechanism, in connexion with such part; the process should be allowed to run its course, or when inadequate, it should be encouraged by maintaining or superinducing the requisite conditions.

.Reparatively, inflammation is available in the healing of incised wounds or fractures, when the soft tissues or the bone are indisposed to unite by non-inflammatory adhesion. Other instances of this kind are cited at p. 44, and many additional illustrations will occur in practice.

Constructively, the plastic operation of lymph-deposit is available for the opening of an abscess safely from a great depth and by a dangerous route; and here also many analogous cases, additional to those noticed at p. 45, are sure to come under the observation of the watchful clinical observer.

Supplemental to the restorative purpose of inflammation, as viewed productively, the destructive aspect of this process may have a similar character. Thus, ulceration forms an opening for the discharge of superfluous organizable material,—pus; and mortification, by sloughing, is useful in loosening and facilitating the evulsion of a foreign body. Obviously in any such case, if interference be necessary, the destruction of textures can be turned to good surgical account.

Whenever the purpose of inflammation is neither reparative, constructive, nor usefully destructive, the process should forthwith be arrested, or subsequently conducted to a favourable issue.

In accordance with the pathology and causes of inflammation, the following are the general indications of treatment to be observed:

(1) The removal of any exciting cause or causes in operation is the

fundamental rule of treatment; bearing more especially on the arrest of inflammation. The causes alluded to comprise the various kinds of irritant matters—mechanical, chemical, and vital—that were enumerated among the “external” causes of inflammation (p. 39); moreover, any constituent of the organism which has become a foreign body, and morbid products, which are more apt to assume that character. They are the “internal” exciting causes of inflammation (p. 39). The significance of their operation, and the efficacy of their removal, as causes of irritation, are well illustrated in the every-day practice of Surgery. Blood, extravasated and decomposing, is a poison; its evacuation is followed by the subsidence of inflammation and constitutional disturbance. A slough of soft textures contaminates; its withdrawal is similarly beneficial. The extraction of a piece of dead bone will arrest a discharge of pus which had continued for weeks, months, or years, and had reduced the patient to the brink of the grave. Excretions are obnoxious when decomposed, and powerfully irritant to parts not intended by nature for their reception;—as urine extravasated into the cellular texture of the scrotum. And the evacuation of excretions under these circumstances arrests the concurrent inflammation. Hence the efficacy of free incisions in the scrotum in the case supposed. Of morbid products, a calculus in the kidney, provokes nephritis; this inflammation ceases when the stone passes down the ureter into the bladder, and is succeeded by cystitis, which in its turn subsides when the foreign body is removed by lithotomy or lithotripsy. These examples will suffice to enforce the general rule of treatment.

Whenever the exciting cause in operation—whether externally or internally—is removable, the process of inflammation not unfrequently ceases with its removal. Fortunately also the fulfilment of this indication meets the requirements of an already large class of cases, and an increasing class as our knowledge and detection of causes becomes yet more early and exact. It is thus that inflammation of local origin may often be arrested, as compared with that which depends on constitutional causes.

In all other cases the process continues and runs its course to structural results if unopposed. The treatment required is no longer preventive only, but counteractive also.

(2) Removal, therefore, of (*a*) the pathological conditions or elements which, co-operating, constitute inflammation; and of (*b*) its local consequences with their concomitant constitutional disorders.

(*a*) The conditions to be overruled by appropriate remedial measures comprise: accelerated textural productiveness, and consequent accelerated textural waste or destruction of texture; the accompanying determination of arterial blood, and any morbid condition of quality in the blood supplied to the inflamed texture or organ; and perversions of the nervous influence.

Experience has established the remedial efficacy of certain measures, both local and constitutional, and which constitute the “antiphlogistic” treatment. This term having been long since recognised in practice, it may be conveniently retained without implying any theory as to the *modus operandi* of the agents employed.

Local antiphlogistic measures consist in the application of cold, heat, or warmth, with moisture, as in the common bread-and-water poultice or moist spongio-piline epithem; in blood-letting by leeches or scarification,

an elevated posture of the part inflamed; incisions, sufficient to relieve tension; blisters, setons, caustics,—as caustic-potash, mineral acids, iodine, burning heat or the actual cautery, and other strong irritants; pressure.

*Constitutional* or systemic measures include—blood-letting by venesection, purgatives, diaphoretics, diuretics, starvation and the antiphlogistic *régime*, antimony, opium, mercury, wine, brandy, ammonia, and other stimulants; cinchona bark, the mineral acids, and other tonics; cod-liver oil, nutritious diet.

Taking this list of remedial agents, some are of the most opposite character, but they may all be used appropriately, in the course of inflammation generally, in the order enumerated.

**LOCAL APPLIANCES.**—*Cold* is more efficacious in the early treatment of inflammation, and as affecting external parts of the body. It may be applied, according to the degree of cold required, by means of ice, or by an evaporating lotion of spirits of wine and water in various proportions. Lead lotion—the liquor plumbi diacetatis, a drachm or more to eight ounces of water—is another refrigerant, but far less serviceable. The application of cold externally will even reach an internal organ, as the brain in meningitis, through the interposed scalp and cranium; but in all such cases the more intense cold of pounded ice in a bladder is necessary to produce a beneficial effect. To some internal organs cold can be applied directly, as to the stomach in gastritis, by swallowing bits of ice.

The leading fact to be observed in every case is, that refrigeration should be continuous and uniform. This two-fold requirement is best fulfilled by some form of self-acting irrigator. A skein of cotton pendant from a bottle of cold water suspended over the part will supply a constant dribbling stream, and thus answer the purpose very well. Its efficiency is witnessed in preventing or arresting inflammation of the large joints. The best rule for the application of cold is to employ it in those cases where, and so long as, the sensation is agreeable to the patient; otherwise to discontinue it.

*Heat*, moderate, with moisture, is preferable in those cases where cold is uncomfortable to the part, or occasions any shivering sensation. Moist warmth is more advantageous also when inflammation is established, the remedial efficacy of cold being restricted rather to incipient inflammation. Warmth and moisture are conveniently applied in the shape of a light, soft bread-and-water or linseed meal-poultice; or by means of spongio-piline soaked in warm water. The latter surpasses any kind of poultice, which is apt to dry, thus becoming an irritant, and is uncleanly. Spongio-piline is even more retentive of moisture than an equal substance of flannel, and more suitable, therefore, as an epithem.

*Blood-letting locally* is advantageous whenever it appears desirable to make a sudden, considerable, and direct impression on an inflamed part, as the eye in iritis. Leeches, scarification, or cupping are available for this purpose. Leeches can be applied to a part which is inaccessible to the cupping-glass, as the os uteri. But the drawing action of a cupping-glass, the pressure of the atmosphere being removed, penetrates to a greater depth than the abstraction of blood by leeches. Hence cupping is more suitable for inflammation of internal organs, as the kidneys when inflamed.

In employing either mode of topical blood-letting, it should be remembered that hæmorrhage may continue for some time after a leech-bite or cupping. An average-sized leech, when fully distended and ready to

drop off, holds about a drachm and a half of blood, and the amount drawn by a cupping-glass can be watched and measured; but the quantity which flows subsequently should always be taken into account and allowed for, more especially with regard to leeches, the after-hæmorrhage from which is more uncertain—by fomentation amounting to half an ounce, or far more, even spontaneously. A single leech has thus proved fatal to an infant. The hæmorrhage is, perhaps, best arrested by touching the little triangular punctured wound firmly with nitrate of silver.

Dry cupping, or the application of an exhausted cupping-glass without previously using the scarificator, is a method of drawing blood to the surface, without abstracting it from the mass in circulation; yet it may be questionable whether the blood thereby rendered stagnant, is not spoilt for the purpose of any returning circulation. The corpuscles are damaged or destroyed, and this change will, of course, be more likely to occur, the more frequently the cupping-glass is re-applied to the same part; so that the blood might as well be withdrawn from the body, as left partially extravasated with its corpuscles broken up.

*Position.*—An elevated posture of an inflamed part is equivalent to the local abstraction of blood. The determination of blood becomes diminished, and the return of blood facilitated; whereby the quantity in the part is greatly reduced. Elevation of posture has, therefore, the same effect as local abstraction of blood, or will, at least, further aid its effect; and this resource is a good substitute for, or a useful adjunct to, local blood-letting. Its efficacy is witnessed in the treatment of inflammation affecting different parts of the lower extremity; as in compound fracture of the leg, dislocation or disease of the knee-joint, and other morbid conditions.

*Incisions* are appropriate to relieve tension; this being caused partly by distension of the blood-vessels in the part inflamed, but principally by the serum effused. Here, then, as with regard to local blood-letting, the guidance of pathology, in the treatment of inflammation, is somewhat available. For the incisions should be made in extent and depth according as either condition of tension predominates. In chemosis, the sub-conjunctival collection of serum suggests the kind of incision necessary. In glossitis, vascular distension is relieved by scarification over the upper surface of the tongue, rather than by one free incision. In phlegmonous erysipelas, both sources of tension are relieved by incisions in different parts of the skin, as the chief seat of vascular distension, and extending down to the subcellular texture, which is engorged with serum. In all cases, however, the requisite length and depth of incisions must be determined practically, by their effect in relieving tension.

Incisions for the discharge of pus and slough will be considered in a subsequent part of the treatment of inflammation.

*Irritants.*—Blisters, setons, caustics, as potass-fusa, the mineral acids, iodine, burning heat or the actual cautery, and other strong irritants, are remedial measures of much value in the more *chronic* forms of inflammation. Their intensity of action varies, but their kind of action is said to be counter-irritant or derivative from the inflamed part, by exciting inflammation in the neighbourhood of that part. This may be true in some cases. In other cases irritants have the opposite effect, they increase the inflammation in the part itself; either bringing it to a termination by resolution, or by promoting effusion and hurrying on the process to suppuration.

According to the object in view, therefore, we should apply any such agent more or less nearly in relation to the part inflamed, and be guided in our choice of one or other by regard to the intensity of its operation.

A seton consists of a skein of silk, worsted, cotton, or hemp thread ; which is attached to the eye of a needle, three or four inches long, and a quarter of an inch in breadth. (Fig. 5.) The integument is pinched up between the thumb and fore-finger, and the needle passed through, carrying the seton-skein after it ; the needle is then cut off, leaving the lash of threads in the subcutaneous track, and either end hanging out.

FIG. 5.

Inflammation is soon excited, with suppuration ; and this counter-irritation and derivative discharge are established for so long a period as it may be desirable to allow the foreign body to remain. If the needle be not at hand, the seton may be passed by means of a common probe : a bistoury having been passed through the fold of integument, the armed probe is slid along the flat of the blade.

A few examples will illustrate the remedial value of this class of agents in inflammation, subject to these two regulations. Blistering the skin is very serviceable in chronic and deep-seated inflammation of the bones and joints. In chronic arthritis, the bulky ends of bone which form the knee-joint and their articular cartilages, are most advantageously influenced by the action of blisters, placed above or below the joint. A seton or issue, which produces a constant discharge of pus from the neighbourhood of the vertebræ, is often of signal service in caries of the bodies of these bones. When applied to the nape of the neck, the same beneficial effect is witnessed in chronic meningeal inflammation of the brain. Of caustics, the potass-fusa is sometimes useful in similar cases, but it is comparatively seldom employed. I rarely use this kind of caustic, and indeed, it seems to be going out of fashion. Nitrate of silver, lunar caustic, promotes the resolution of a whitloë, a bunion, a hordeum or sty in the margin of the eyelids ; and such like intractable conditions of inflammation. Of the mineral acids, as caustic appliances, nitric acid, undiluted, is of great service for converting phagedænic ulceration into inflammation with healing granulations ; but this is scarcely an appropriate illustration as to the treatment of inflammation itself. Iodine "paint," consisting of equal parts of iodine, and of iodide of potassium, to two parts of rectified spirit, and four parts of water, is a strong irritant, of considerable value in removing the effusion and indura-

tion attending chronic inflammation generally. Various stimulating embrocations, as camphor and ammonia, with olive oil, are thus used. The actual cautery may be resorted to, with marked benefit, occasionally, in cases of deep-seated and chronic inflammation affecting the joints and bones, and especially the vertebræ. Thus also the burning-moxa was formerly in some repute. Placed over the spine, and allowed to burn down, it produces a circular slough of skin about the size of a shilling or half-crown. Several moxæ were sometimes applied in a row, simultaneously. But the remedial efficacy of such a powerful counter-irritant measure as even one moxa, is very doubtful; while the severe and continued pain is a decided disadvantage, and more so in virtue of its tendency to aggravate inflammatory fever.

This consideration, indeed, restricts the use of the more powerful kinds of counter-irritants. Unlike the pain caused by the clean cut of a knife in most surgical operations, the pain induced by strong cauterization is felt when the influence of the chloroform has ceased, although the part itself may be killed outright. "It deserves full trial," observes Mr. Simon,\* "whether every intense, and consequently painful form of counter-irritation, might not be superseded by the employment of other means, less intense, but more extensively applied; whether, for instance, ten inches of poultice, may not be equivalent to four inches of blister, or to one inch of issue." In respect to thoracic inflammation, for example, where blistering is employed as a matter of routine practice, the unsurpassed clinical authority of Professor Skoda pronounces such treatment to be always useless, sometimes hurtful.

Re-investigation, therefore, is more especially needed here; further experience, guided, if possible, by the light of pathology.

CONSTITUTIONAL REMEDIAL MEASURES.—*Systemic blood-letting*, by venesection. This mode of depletion has fallen nearly into disuse, in the treatment of inflammation.

The explanation of this change of practice on the part of the Profession generally, is referable to two entirely different views, each having its partisans. According to one school, so to speak, the human constitution has itself undergone a great change in the loss of vital power, whereby febrile symptoms have altered from an inflammatory to a typhoid character. The late Dr. Alison† was the champion of this doctrine. On the other hand, it is contended, that the principle on which blood-letting had hitherto been practised is opposed to Pathology; and that our more advanced knowledge of this science has led to its abandonment. This explanation is offered and ably advocated by Dr. J. H. Bennett.‡

Assuredly the change of practice has taken place, and experience sanctions its propriety. As to its interpretation; probably in regard to this, as to many vexed questions, both parties are partly right, and partly wrong.

But it is not only in the present as compared with former practice, in one period as compared with another, that differences of opinion have prevailed respecting the remedial value of general bleeding in inflammation; it is no less remarkable—as Mr. Simon observes—that contemporaries living under the same sky, and practising in the same year on the same disease, have waged controversy on this subject; and not unfrequently it has seemed probable that medical juries, inquesting any

\* Op. cit., p. 103.

† Edin. Med. Journ., 1856, March.

‡ Principles and Practice of Medicine.

given dead patient, would divide in equal numbers, whether much bleeding or little bleeding had killed the man.

In explanation of this anomaly the same author urges; that, practically, all impartial observers seem now to agree, that while there are inflammations which bleeding can relieve, yet there are also inflammations which every act of depletion, instead of diminishing, will increase. And the obvious inference from this fact is one which, certainly, the pathology of inflammation would indicate; that the therapeutical value of blood-letting does not so much consist in its directly controlling inflammatory excitement, as in its controlling some condition, which may or may not be concomitant.

What then is this condition? Reserving for a moment that which Mr. Simon suggests, I would first notice another.

Forcible contractile action of the heart, with a strong pulse, undoubtedly maintains the local determination of blood; although this latter may be aided by the accelerated nutritive changes of the part itself, using up the plasma supplied, and thereby continuously eliciting exudation from the capillary vessels.

General blood-letting, by venesection, powerfully relieves the action of the heart, even to syncope. But, with inflammatory fever, the system is more tolerant of loss of blood than in health, or other diseases. This increased tolerance was first clearly shown by Dr. Marshall Hall, the results of whose investigations are given in the following table, which represents as compared with health, the mean quantity lost before incipient syncope is induced, the patient being in the sitting or the erect posture:—

#### 1. Healthy Tolerance:

This depends on the age, sex, strength, &c., and on the degree of thickness of the parietes of the heart; but it is about . . . . .  $\frac{3}{4}$  xv.

#### 2. Increased Tolerance:

Congestion of the brain . . . . .	$\frac{3}{4}$ xl—l.
Inflammation of serous membranes . . . . .	} $\frac{3}{4}$ xxx—xl.
Inflammation of synovial membranes . . . . .	
Inflammation of fibrous membranes . . . . .	
Inflammation of the parenchyma of organs— brain, lung, liver, mamma, &c. . . . .	$\frac{3}{4}$ xxx.
Inflammation of skin and mucous-membranes, erysipelas, bronchitis, dysentery . . . . .	$\frac{3}{4}$ xvi.

#### 3. Diminished Tolerance:

Fevers—eruptive and others. . . . .	$\frac{3}{4}$ xi—xiv.
Delirium tremens, and puerperal delirium . . . . .	$\frac{3}{4}$ x—xii.
Laceration or concussion of the brain . . . . .	} $\frac{3}{4}$ viii—x.
Accidents, before the establishment of inflammation . . . . .	
Intestinal irritation . . . . .	
Dyspepsia, chlorosis . . . . .	$\frac{3}{4}$ viii.
Cholera . . . . .	$\frac{3}{4}$ vi.

The condition to which Mr. Simon refers as deserving especial notice, is that state of the vascular system, which, often designated “vascular tension,” is characterized by a hard pulse.

Both these conditions—forcible action of the heart and vascular tension—are alike diminished by general bleeding; the pulse becoming weaker, slower, perhaps more regular, and softer.

The propriety of having recourse to this reducing measure should

therefore be determined and regulated by reference to the state of the general circulation, as indicated by the characters of the pulse in respect to its force and hardness. But the necessity for blood-letting is proportionate also to the physiological importance of the organ affected, which might otherwise be permanently damaged by the structural results of inflammation; and the urgency on this ground will be indicated by the functional disturbance which the organ itself suffers and induces by its functional relation to other organs. These conditions of organic significance are not accompanied with a corresponding tolerance of blood-letting. For example, they co-exist in pneumonia, especially double pneumonia; the lungs being highly important organs functionally, dyspnoea and general functional disturbance thence arises. Yet in this disease the tolerance of blood-letting is thirty ounces, as shown by the table, or only double that of health, and less by twenty ounces than that of the highest range in the list.

The effects of blood-letting are more than momentary. This should always be remembered in considering the necessity for producing a powerful and persistent impression on the general circulation. Such impression can be made in either of two ways; the one or the other having a salutary tendency, according to the previous duration of the inflammation.

Recent inflammation may be arrested by the loss of a moderate quantity of blood, suddenly—*i.e.*, through a large orifice or from both arms simultaneously, and the patient being placed in the sitting posture, so as to induce syncope.

Inflammation of a few days' duration will be more surely brought to a termination by the loss of a larger quantity of blood, gradually; the bandage above the orifice in the vein being loosened, and the patient in the recumbent position, to avert the tendency to syncope. Or venesection may be repeated from time to time, according to the symptoms; thereby renewing and further maintaining the impression originally made on the circulation.

The advantage of gradual over sudden loss of blood, in inflammation of some duration, is evinced by the fact, that if the first impression be thus maintained, it is found unnecessary to repeat it.

Local blood-letting will prove sufficient subsequently, in most cases; and advantageously so, by directly affecting the inflamed part without powerfully and persistently influencing the system. And it should never be forgotten, that the permanency of systemic impression is directly proportionate to the quantity of blood lost. Nutrition is reduced throughout the body, and any process of reparation may fail. Probably the vital injury of excessive blood-letting or of such hæmorrhage accidentally, is never quite recovered from.

*Purgatives* not only remove fæculent matter, which would otherwise be a source of irritation affecting also a large extent of intestinal mucous membrane; but, their operation is depletory by inducing the discharge of serum from the blood. Purgatives are, therefore, a useful adjunct to, or even a substitute for, general blood-letting, in relieving vascular tension. Different kinds of purgatives appear to act on different portions of the intestinal tract; and hence a combination of these medicines may prove more efficient than any one alone. Salts and senna, jalap and rhubarb, are familiar examples of such combinations. It would be very desirable to acquire more extensive and exact knowledge respecting the action of purgatives for this purpose.

But they probably have also different selective powers, in promoting the discharge of different constituents of the blood, and various effete or noxious matters; thus affecting the quality as well as reducing the quantity of the blood in circulation. Here, more especially, further clinical observation would be highly desirable.

Besides removing irritant matter, and having a depletory and an excretory operation, purgatives are said to have a derivative action, apparently by inducing hyperæmia of the intestinal mucous membrane. In this way they are supposed to antagonize inflammation of the brain, for example. But it is a kind of action which prohibits the continued use of purgatives, lest intestinal inflammation be superinduced.

The purgative operation of mercury is referable to its agency in promoting the secretion of bile,—itself a natural purgative. Besides, however, having this effect, the “cholagogue” action produced by larger doses of mercury is equivalent to general blood-letting as a depletory, and superior as an excretory, remedy; for the copious spinach-like evacuations produced are equally effectual in reducing vascular tension, and are specially excrementitious, without unnecessarily diminishing the quantity of blood in circulation. Calomel, in doses of five, ten, or twenty grains, and repeated as occasion may require, is perhaps the best cholagogue.

The action of mercury on the liver as a secreting and excreting organ, suggests a general inquiry respecting the action of other purgatives, specially on the glandular apparatus of, or associated with, the gastro-intestinal organs. What medicines specially affect the secretion of the pancreas; what, with regard to the glands of the gastro-intestinal mucous membrane; namely, the tubular, the cardiac, and the lenticular glands of the stomach; the glands of Brunner, the crypts of Lieberkuehn, and Peyer's glands, of the small intestine; and the innumerable follicles of the large intestine?

*Diaphoretics* and *diuretics*—medicinal agents which increase or alter the secretions of the skin and kidneys, respectively—are purgatives in their way. They are depletory, excretory, and derivative. Such is the acetate of potash, a diaphoretic, and the nitrate of potash, a diuretic. Little or nothing is known of these, and similar medicines, in their intimate relation to inflammatory fever. Experience alone sanctions their use. Their administration constitutes what is more particularly designated “febrifuge” treatment. A liberal allowance of water, soda-water, or other bland fluid, seems to favour the excretory operation of these medicines; probably by diluting, and, as it were, washing away effete matters from the system.

*Starvation* is another kind of depletion, by withholding the supply of nourishment. And if this were all that the term suggests physiologically, its significance therapeutically in relation to pathology, would be very simple. But starvation has reference to many differently constituted textures; each undergoing its own nutritive changes, and having its own food requirements. Consequently, the starvation of any one kind of texture, and kindred textures, is physiologically possible without, at least proportionately, depriving others of their food. Thus, the albuminoid textures, of which muscle is the type, might be starved, apart from the gelatinous, as skin and mucous membrane; and these again apart from osseous texture. The various artificial preparations of food have not, however, hitherto reached this desideratum of composition, for the purposes of therapeutic treatment, yet it would bear very directly on inflam-

mation,—accelerated nutrition,—as affecting different organs and their component textures. The “antiphlogistic regimen” is rather a negative than a positive regimen. Dietetically, it consists in abstinence from animal food and stimulating drinks, and in the moderate use of bland fluids, as barley-water, gruel, arrow-root. But it also implies the exclusion of all surrounding circumstances of excitement to mind or body. A cool and well-ventilated apartment, an easy bed, exclusion of light and noise, the prohibition of conversation, of the constant presence and attention of friends, and the banishment if possible of care; such are the principal features of this regimen.

*Antimony*, as an internal remedy, most nearly resembles general blood-letting. After a dose of say, half a grain, repeated or increased to one or even two grains, every three hours, until vomiting occurs; the effect on the circulation and secretions are very marked. At first, the pulse becoming more rapid and feeble, it dwindles down to a fine thread. Then, vomiting having occurred, the pulse loses its frequency, and perhaps regains its force, but acquires a peculiarly full and soft character; showing that vascular tension is overcome or relieved. Simultaneously, perspiration and the secretion of urine are notably increased; and liquid evacuations from the bowels not unfrequently accompany this relaxation. The muscles also are flaccid and powerless. In short, the whole muscular system, voluntary and vascular, is relaxed; and a flux or flow takes place from various secreting organs, which further reduces the vascular tension. Any local inflammation is thus materially diminished.

A full dose of tartarized antimony having this result; similar effects, though in a less marked degree, and without the distress of vomiting, may be produced by smaller doses. Fortunately, however, vomiting soon ceases, while the beneficial influence continues with the full administration of the medicine; or this symptom may be controlled by administering it in the form of a saline draught with four or five minims of diluted hydrocyanic acid. The action of this remedy is most salutary when even nausea is not induced.

Antimony will be most advantageously prescribed after general blood-letting to maintain its effects, and in proportion as the vascular tension, indicated by hardness of the pulse, continues. But either resource may be considered a substitute for the other; and experience gives the preference to antimony, generally. It is found to be most effectual in pneumonia, orchitis, and inflammation of other unyielding textures; less so with regard to serous membranes; and it is contra-indicated in enteritis.

*Opium* is of signal service in the treatment of inflammation. It seems to act partly like antimony and blood-letting by overcoming vascular tension, but opium has the advantage of also subduing nervous excitement. Its administration is, therefore, most appropriate when this is the predominant element in inflammatory fever; or when excitement of the circulation declining, that of the nervous system with general weakness become prominent. It is thus that opium proves so beneficial after severe injuries or surgical operations; where shock is followed by excessive reaction, or prostration with excitement prevails over or outlasts inflammatory fever.

In some cases, opium acts specially on the part injured or operated on, as by paralyzing the peristaltic movements of the intestine after the operation for strangulated hernia. It seems also to influence, in some

way, favourably, inflammation having an ulcerative or gangrenous tendency.

The chief disadvantages attending the use of opium are ; the sickness it is apt to occasion at first, and constipation by its more continued use. The latter can be controlled or prevented by our next remedial measure, prescribed in combination with the opium.

*Mercury* counteracts the constipating tendency of opium, and this, in its turn, overrules the aperient action of mercury ; either medicine checking the intestinal influence of the other. The combination generally employed is calomel and opium ; in the proportion of from one grain to five of the former, with a quarter of a grain to one grain of the latter, given as a pill every four hours or so.

But does the continued administration of this familiar formula produce any remedial effect, through the systemic influence of mercury ? This is debateable ground. Unquestionably, mercury can be introduced into the system—meaning thereby the blood in circulation—and it then produces peculiar symptoms ; the gums becoming red, spongy, and tender, the breath having a peculiar fœtor, and a metallic taste being experienced like that of copper in the mouth. The salivary glands under the tongue and at the angle of the jaw become somewhat swollen and painful, and the secretion of saliva increased. This associated group of symptoms, constituting “salivation” or ptyalism, announces that the system is under the influence of mercury. Mercurial infection, or “mercurialism,” as it is called, is in fact attested by the supervention of certain symptoms ; just as the introduction of the syphilitic virus, for example, is followed, in the course of time, by enlargement and ulceration of the tonsils, some definite skin eruption, and perhaps iritis ; symptoms declaring the syphilitic infection to have taken place.

So far then there are certain effects, specially due to the systemic influence of mercury.

Formerly, also, and until recently, it was unanimously held, that the same influence prevented or retarded the effusion of fibrin, and promoted its absorption. That, “the constitutional action of mercury opposes the organizing efforts of inflammation,” is the somewhat equivalent expression of Mr. Simon. Does this represent the remedial virtue of mercury in the systemic or constitutional treatment of inflammation ? A good illustration of such influence was supposed to be, the visible disappearance of lymph in iritis, apparently under the operation of mercurialism.

Long as this therapeutic theory prevailed, and practice accordingly ; there are reasons for doubting the accuracy of the one, and the efficacy of the other. That mercury exercises some kind of influence over nutrition, there can be no doubt ; but it is questionable how far the natural course of inflammation, having induced the effusion of fibrin, may itself tend to absorption, apart from the co-operation of mercury. Mr. Simon limits the agency of mercury by the following qualifications ; that, “if mercurial cachexia in its lesser degrees, and independently of the purging which may attend it, has a real effect on inflammatory products, this effect probably relates only to such products as are not organized, and perhaps is nothing more than the giving of some special assistance to the dissolution and removal of fibrin.”

Further clinical investigation is needed to determine the question at issue.

Assuming the systemic influence of mercury upon inflammation; its remedial operation can be insured only, by employing it in a certain class of cases, and with certain precautions.

Both these practical requisites are generalized by Sir Thomas Watson, thus:—

“In common adhesive inflammation, whether of the serous or areolar tissues; whenever, in fact, you have reason to think that coagulable lymph is effused, and mischief is likely to result from its presence, then you may expect benefit from the proper administration of mercury; as an auxiliary, however, to blood-letting, when blood-letting is indicated, not as a substitute for it. . . . Previous blood-letting renders the body more readily susceptible of the influence of mercury; and the operation of the mercury comes in aid of the salutary effects of the abstraction of blood. The two remedies accomplish by their joint power what neither of them might be able to accomplish singly.”

“On the other hand, mercury is likely to be hurtful in those forms of disease, where the morbid action approximates to its own action; in cases of erysipelatous inflammation having a disposition to gangrene; in scrofulous diseases; in inflammatory complaints attended with general debility, and an irritable condition of the nervous system, or a manifest tendency to take on a low and typhus-like character.” On behalf of the scrofulous diathesis, it is added; that moderate salivation may prove salutary during an attack of common inflammation; and as surely injurious if the inflammation be scrofulous.

“When we have to contend with acute inflammation, and desire to prevent or arrest the deposition of coagulable lymph, our object is, after such bleeding as may have been proper, to bring the system as speedily as possible under the specific influence of mercury.”

“We know that the whole system has been brought under the specific influence of mercury, as soon as its effects become even slightly perceptible in the gums and breath of the patient; and in adults we cannot be sure of it before. These symptoms are enough; you need not in general look for any more decided affection of the mouth, such as ulceration of the gums, swelling of the glands beneath the jaw and the tongue, and a profuse flow of saliva. . . . All that is requisite is, that the gums should become distinctly tender, and that the mercurial fœtor should be unequivocally manifest, and that these symptoms should be kept up for a certain time. Now this is best effected, usually, by giving some form of mercury in equal and repeated doses by the mouth. For urgent cases, calomel is the best form in which it can be administered; two or three grains given every four or six hours, will generally suffice to touch the gums in the course of thirty-six or forty-eight hours. If it act as a purgative, its specific effect upon the whole system will be postponed by that circumstance; and it then becomes expedient to combine it with just so much opium as will prevent it passing off by the bowels. A quarter of a grain of opium with two grains of calomel or a third of a grain of opium with three or four grains of calomel, will generally be sufficient to restrain the purgative operation of the latter. When a speedier effect is desirable we give larger doses; such as five or ten grains every three, or even every two hours; or we combine mercurial inunction with the exhibition of calomel by the mouth. It is impossible to lay down any precise rule that will fit all cases. Blue pill, or else the

hydrargyrum cum creta, may, in certain cases, be preferable to calomel; but they must be given in greater quantity."

"Mercury is of great service in many cases of chronic inflammation; and I may repeat here the observation I formerly made when speaking of blood-letting—that the treatment must keep pace, as it were, with the disease. When textures have been slowly altered by a gradual deposition of coagulable lymph, we should gain little or nothing by suddenly or speedily salivating our patient. The lymph, if it can be dispersed at all, must be gradually taken up again: and mercury, given with the view of promoting its absorption, must be slowly and gradually introduced into the system, and its specific influence, when at length it is felt, must be sustained for a considerable length of time."

Certain evil consequences are apt to follow the use of mercury. In fact, the symptoms of systemic infection by this mineral have a general resemblance to those of constitutional syphilis, or systemic infection by the syphilitic virus. But as, in most cases, the unfavourable action of mercury is fairly attributable to its immoderate or prolonged administration—an error of rare occurrence, now-a-days—it is scarcely necessary to consider the treatment of mercurial poisoning.

Profuse salivation is, however, an exception which merits attention. Some persons are very easily salivated. In one case—related by Dr. Farre—a lady was affected furiously, in a few hours, by two grains of calomel; prescribed as a purgative with some cathartic extract. She died at the end of two years, worn out, and having lost portions of the jaw by necrosis. Intense salivation is best relieved by the application of a few leeches to the swollen and painful glands. Smearing the gums with powdered tannin, will probably reduce their engorged condition, and give additional comfort. Gargling the mouth with weak brandy-and-water is another resource, not unfrequently successful in relieving the distress. Chlorate of potash, taken internally, is spoken of very favourably by Herpin, M. Ricord, M. A. Fournier, and Mr. Simon, as far as his trials of it have gone. The doses given were commonly ninety grains during the day; and it is expressly stated, that, while the inflammation of the mouth was thus effectually cured, the therapeutical influence of the mercury was in no degree diminished.

On the other hand, some persons are very difficult to salivate. Such cases are not uncommon, and unfortunately they seem most apt to occur when the controlling agency of mercury is most urgently required. In syphilitic cases of obstinate resistance to mercurialism, Mr. Simon finds that this insusceptibility often gives way, if tartarized antimony be administered in conjunction for a day or two; a half-grain dose, and then a few quarter-grain doses at eight-hour intervals.

*Stimulants.*—Wine, brandy, ammonia, or other stimulants, are necessary; whenever inflammatory fever has passed into a state of general depression and exhaustion, the natural sequence of nervous and vascular excitement. Requisite, therefore, as stimulants may be in proportion to the weakness manifested at even an early period; they are sure to become indispensable as the fever itself subsides. And on account of the local condition also, stimulants may be appropriate. When, in the course of inflammation, productiveness predominates, in the shape of effusion and suppuration, it will be necessary to support the circulation under the demand then made; and when destructiveness

predominates, it will be even more imperative to sustain all the vital powers under the influence of poisonous matters absorbed in the course of suppuration, pyæmia, ulceration, or sloughing.

The "genuine effects of stimulation" are thus generally enumerated by Dr. Anstie,\* who has made this the subject of elaborate inquiry; but who, it must be confessed, has arrived at conclusions opposed for the most part to those of previous authors, and which are open to farther clinical investigation. The effects observed are eight in number:—"relief of pain; removal of muscular spasm, tremor, or convulsion; reduction of undue frequency of the circulation; reduction of excessive secretion; removal of general debility, or of special fatigue of the muscles, brain, or digestive organs; removal of delirium, or maniacal excitement, and production of healthy sleep; support of the organism in the absence of ordinary food; local increase of nutrition where this is deficient."

In regard to one of these effects, at least,—“reduction of undue frequency of the circulation,” this view of the action of stimulants would be antagonistic to the propriety and efficacy of administering them for the exhaustion consequent on inflammatory fever.

If we would proceed yet farther, and endeavour to analyse the action of stimulants and interpret their operation, physiologically and therapeutically; we encounter greater difficulties, and are led, at present, to the most irreconcilable conclusions. Pereira classes stimulants under the general head of neurotic remedies (acting upon the nervous system), and under the special class of Ganglionics (acting upon the sympathetic system). He adopts the definition of Dr. Billing; “a stimulant is that which, through the medium of the nervous system, increases the action of the heart and other organs, by calling forth the nervous influence, or by facilitating the extrication of it in them.” The definitions of Dr. Neligan,† and Dr. G. B. Wood‡—one of the authors of the “United States’ Dispensatory,” are both to the same effect. On the other hand, Dr. Anstie proposes; “that the use of the word ‘stimulant’ be restricted to agents which, by their direct action, tend to rectify some deficient or too redundant natural action or tendency; and, that agents which produce excessive and morbid actions of any kind in the organism, be refused the name of stimulants, even though smaller doses of them may act in a truly stimulant manner. That, the word ‘over-stimulation’ be entirely rejected from use, as unphilosophical and a contradiction in terms”||

The kind and quantity of stimulant or stimulants appropriate, will vary greatly according to the age, constitutional strength, previous state of health and habits, of the individual. But the consideration of these particulars had better be left to the special experience and judgment of the practitioner.

*Tonics.*—Cinchona bark, the mineral acids, sulphuric, nitric, nitromuriatic, and other tonics; are useful under, perhaps, similar circumstances to those requiring the aid of stimulants, in the treatment of inflammation. Yet these two classes of remedial agents have different, perhaps opposite, effects, in some respects, although it is difficult to distinguish their operation in every particular.

\* Stimulants and Narcotics, 1864, p. 113.

† Medicines, their Uses and Modes of Administration, ed. 4, p. 348.

‡ Therapeutics and Pharmacology, p. 48.

|| Op. cit., p. 161.

A stimulant certainly produces its effects suddenly and transiently; a tonic, its effects more gradually and more permanently. Then again, the chief primary effect of the one, is to quicken the circulation, as manifested by increased rapidity of pulse; while, the chief primary effect of the other, is to strengthen the circulation, and hence an increased force of pulse.

Thus far these two kinds of agents contrast.

Both, however, concur, in restoring the balance of the circulation from the depression connected with or consequent on the subsidence of inflammatory fever; and subsequently, in contending against the exhaustion of continued effusion or profuse suppuration; or again, in overcoming the depression arising from absorption of poisonous matters, in the course of suppuration, pyæmia, ulceration or sloughing.

The mineral acids seem to exercise a special influence on the secretion of the skin, and indeed, the secretions generally. After having administered the sesquicarbonate of ammonia, as a stimulant, with the tincture of bark or the disulphate of quinine, as a tonic, when first weakness supervenes; the ammonia should subsequently be exchanged for,—say, the diluted nitro-muriatic acid; this tonic combination of bark and acid, being the most effectual means of restraining the sweats of hectic fever, and of cleaning the furred tongue in gangrenous typhoid fever. The general improvement is often very remarkable, and permanent.

*Cod-liver oil*, and *nutritious diet*, are naturally associated; the one seeming to renovate the power of assimilation, the other supplying the materials for restoration. Both become appropriate, and nutritious diet absolutely necessary, on the subsidence of inflammatory fever, and during hectic, pyæmia, and gangrenous typhoid fever; whether for the reproduction of new blood and the general renovation of textural nutrition, or for the reparation of any local deterioration of texture, or loss of substance, consequent on inflammation.

Cod-liver oil may be regarded, partly, as a kind of food, supplying a limpid fat which passes easily into the circulation. In the first instance, it is not unfrequently rejected by the stomach or bowels. Beginning, therefore, with a moderate dose, not exceeding a teaspoonful, of pale, transparent, inodorous, and almost tasteless oil, taken twice or three times a day; this quantity may be gradually increased to a table-spoonful. It is best taken in a little milk, as an emulsion, or floating on orange-wine, ginger-wine, or other light cordial. The addition of a little diluted nitric acid is highly recommended by Dr. C. J. B. Williams;\* or if the tendency to nausea be extreme, the thirtieth or fortieth of a grain of strychnine in solution, with each dose of oil, will be found an excellent corrective. A further precaution is, that the oil be taken ten or fifteen minutes after a meal.

The expression “nutritious diet,” can scarcely be defined. It is assuredly the opposite to “antiphlogistic diet.” Nutrition in the abstract, implies an adequate supply of all the proximate elements which form the textures and organs of the body; whereas the demand arising from inflammation must vary with the particular part affected. Nutritious food, of some kind, will be most needed in proportion to the supervention of suppuration, possibly profuse, and sloughing, possibly extensive. And experience, rather than any chemical knowledge, suggests an in-

\* Principles of Medicine, 3rd ed., p. 490.

creased proportion of animal food, with a liberal allowance of ale or porter, as malt beverages, besides alcoholic stimulants.

(b) *Removal of the Local Consequences of Inflammation.*—They are—productively,—effusion and its organization, suppuration, and the formation of abscess; destructively,—ulceration, sloughing and mortification. As connected with inflammation, it would be unpathological to regard these local consequences otherwise than as continuations of this process; terminally, it is true, yet continuations of one and the same process, essentially.

The local remedial measures, therefore, which counteract the constituent elements of inflammation, are preventive of these after conditions.

But the removal of inflammatory products yet remains to be considered. By what special local proceedings can this indication be accomplished?

Two ways of removing any new product, or any former part of the body, are possible. By absorption, and by evacuation; the latter implying some operative interference.

*Effusion*, consisting of serum, fibrin, and exudation corpuscles, may be dispersed by a stimulating embrocation of ammonia and olive oil, or of camphor and soap liniment; by mercurial ointments, such as the unguentum hydrargyri nitratis; by the compound tincture of iodine, or by "iodine paint;" and by spirit lotions. The influence of some of these agents is aided by the friction employed in their application. Pressure, uniformly applied by even bandaging, will also promote absorption; and this may be aided by some stimulating agent used conjointly, as Scott's ointment to an enlarged knee-joint.

Absorption, is however, available only in chronic inflammation.

Incision will be appropriate when the inflammation is acute, and accompanied probably with considerable tension, as in phlegmonous erysipelas. In all such cases stimulating applications are inadmissible; both by reason of their nature, and the time required for their operation.

*Suppuration* becoming inevitable in any case, the secretion of pus should be encouraged, by quickening the inflammatory process. Abstaining, therefore, from the further use of any remedial measures for counteracting inflammation; the formation of pus is best insured by warmth and moisture topically applied, as by a light poultice, or moist spongopiline.

Absorption of pus is possible. Serum, the fluid portion of pus, is thus readily removed. Pus-cells must undergo a preparatory change. They disintegrate and re-enter the circulation; or remaining, in part at least, the broken-down pus-cells aggregate and form a cheese-like matter, which may at length become cretaceous. Instances of such absorption not unfrequently occur, and authentic cases are recorded by Messrs. Hilton, Birkett, and Critchett;\* and one by Mr. Lawrence.†

The probability of absorption taking place, is but little available for any practical purpose.

*Abscess*, or a collection of matter, generally tends to point, and the surgeon should then follow the footsteps of nature.

An incision, whenever and wherever *pointing* presents, and of sufficient extent to make a *free* opening for the evacuation of matter, and

\* Med. Times and Gazette, 1858, p. 295.

† Surgery, Ed. by T. Holmes, vol. i. p. 142.

its discharge as secreted subsequently; is the rule of treatment. Abscess in certain situations should be opened *early*; indeed, the surgeon cannot be too alert. Thus, in parts abounding with loose cellular texture, as the neck, axilla, groin, neighbourhood of the rectum and vagina, popliteal region, and generally in the cellular planes between muscles. So also suppuration underneath unyielding fibrous expansions, and in the sheaths of tendons. Then again, when adjacent to important organs; as the trachea, pharynx, thorax, abdomen, urethra, and joints. Abscess, moreover, arising from irritant matters; as by the extravasation of urine, or fæces, should be promptly set free. Abscess in situations less accessible, although urgent, perhaps, in other respects, requires some delay; as with regard to the lungs, liver, spleen, kidneys, and most internal organs.

A *dependent* opening, in order to facilitate the after escape of pus, has been particularly recommended,

FIG. 6.

rather than an opening in the situation of pointing. But this practical injunction may be observed too absolutely; for wherever matter points, there, ultimately, an opening will take place. If necessary, however, a dependent *counter*-opening may also be made, to insure the ready discharge of pus as it forms.

To discover the presence of pus, the mode of opening an abscess is important. By introducing a bistoury perpendicularly, a drop of matter wells up along the side of the blade, or a half-turn of the instrument will enable it to do so. The puncture thus made is then readily converted into an incision of sufficient extent. (Fig. 6.)

Thick and flaky pus, and especially when situated deeply, requires a proportionately more extensive incision. Extrusion of any texture, as muscle or fat, hindering the free evacuation of pus, may be obviated by inclining the blade of the bistoury, instead of withdrawing it, as the matter flows.

Hæmorrhage is usually slight and temporary. But in puncturing a deep-seated abscess, there may be some danger. Mr. Hilton, therefore, recommends that an incision be made through the integuments and fascia, so as to expose any muscle under which the pus lies; the cavity of the abscess should then be penetrated by a director, along the groove of which, as a guide, a slender pair of dressing forceps being introduced, the blades are opened, the muscular fibres separated, and free exit is safely given to the pus.

Sometimes, the nature of a swelling or tumour may be doubtful; whether it be solid or fluid, and if the latter, whether an extravasation of blood, or an inflammatory effusion or pus. To clear up the diagnosis, before making an opening with a bistoury to discharge any such fluid matter, it may be advisable to introduce a grooved needle. (Fig. 7.) A

drop of fluid wells up along the groove, or any solid organized material lodged in the groove, is abstracted by withdrawing the needle; and either product can then be examined by the naked eye or under the microscope. I often have recourse to this procedure.

FIG. 7.

The admission of air is generally of serious consequence. Hence some precaution must be observed in opening any *large* and *chronic* abscess. A valvular aperture—as originally proposed by Abernethy—is the best safeguard. Having drawn the skin well to one side, a bistoury is introduced perpendicularly, as usual, but ere the matter has entirely ceased to flow, the integument is allowed to regain its former position; thus obliquely overlaying the aperture in the cyst. The external opening no longer directly communicating with the internal, any matter will continue to drain away without the ingress of air. Moreover, only so much pus escapes as may be discharged by the collapse of the walls of the abscess. When the cavity has partly refilled, the same operation is repeated, and as often as may be necessary for the cyst to contract securely and finally close.

Whether an abscess be acute or chronic, small or large, any thumbing or squeezing would be an unpardonable injury to the delicately organized and highly vascular lining membrane, which previously pus-forming should now become lymph-producing for reparation. On one occasion, having opened a large chronic abscess, situate over the gluteal region, I took the liberty of introducing my finger; deeming it advisable to do so, for the double purpose of turning out the uncommonly thick flaky matter, and of ascertaining whether the cyst communicated with dead bone; the case, a rare one, having simulated either disease of the hip-joint or of the sacro-iliac.

The subsequent escape of matter can, if necessary, be facilitated by the employment of a “drainage-tube,” as recommended by M. Chassaignac. It is a small indiarubber tube with lateral holes; and this pipe may be passed into the abscess leaving one end hanging out, or drawn through the abscess by a counter-opening and both ends tied together. The objection to this proceeding, is the irritation caused by the tube, as a foreign body. In fact it is a seton.

The dressing of an opened abscess should be unirritating. A light poultice may be applied to encourage the discharge of pus, during the process of granulation from within; or the application of a piece of lint to close the aperture, as soon as possible, will be appropriate, when the abscess is to be reopened from time to time.

Abscesses by “translation,” and “secondary abscesses” in the course of pyæmia, should be treated as chronic abscesses; and the more so the larger the size to which they have attained. A valvular opening therefore should be made, and closed with a piece of lint after the tension of the sac is sufficiently relieved, this being repeated when necessary. Obviously such treatment relates only to external, or at least to accessible parts.

*Sinus* and *fistula* require special treatment, in some respects. Any

assignable cause having, if possible, been removed; pressure by a graduated compress and bandage, will succeed occasionally in bringing about adhesion; if the sinus or fistula be recent and accessible. When induration has taken place, or pressure cannot be applied; stimulating injections of sulphate of zinc or nitrate of silver, sometimes answer the purpose. Or a red-hot wire introduced up the passage, may prove successful. This is conveniently accomplished by Mr. Marshall's apparatus; whereby a platinum wire, introduced cold, is made red-hot instantaneously by the galvanic current. Generally speaking, however, sinus or fistula having become indurated, it obstinately resists any attempt to excite adhesion. Slitting up the passage with a curved bistoury, on a director if necessary (Figs. 8 and 9), and healing by granulation from the bottom, must then be had recourse to. A familiar illustration is the operation for fistula in ano.

FIG. 8.

FIG. 9.

The destructive consequences of inflammation—*i.e.*, ulceration and sloughing or gangrene, severally present certain indications of treatment.

*Ulceration*—as depending on inflammation—may be arrested by counteracting any of the constituent elements of inflammation, which are still in operation. Local antiphlogistic treatment—including rest and an elevated position of the part, is indicated. During reparation, the process of suppurative granulation needs little or no assistance. Warmth and moisture, by means of a light poultice, or spongio-piline epithem, may be continued while the chasm is filling up; rest and position being still observed. Superfluous organizable material—pus, is discharged; and when the granulations have grown to the level of the skin, and are no longer suppurative, the aid of a poultice may be discontinued. Water-dressing, simply to exclude the irritating action of the air, is then alone necessary. This application should be exchanged for some slightly stimulating wash, if the pale and flabby state of the granulations suggests the propriety of so doing. A weak solution of sulphate of zinc answers very well. The pressure of a bandage will aid its effect, and repress any exuberant growth.

*Sloughing* and *gangrene*, are, in like manner, amenable to local antiphlogistic treatment, with the view of arresting the process of destruction.

*Effusion*—always an essential constituent of inflammation—is here the element, in particular, to be counteracted or its effect overcome. The relief of tension is imperative. Hence, incisions as free as may be necessary, are the primary indication of treatment. Its efficacy is witnessed in phlegmonous erysipelas and carbuncle.

The process of separation of the living from the dead textures, must

be encouraged. Warmth and moisture, by a poultice or spongio-piline epithem, or the more stimulating action of a yeast poultice, will be highly serviceable, both in limiting the sloughing and inducing the detachment of slough. The latter kind of poultice has the advantage of destroying the factor of decomposing textures. Charcoal in powder, chlorides of lime or zinc, and carbolic acid, are also valuable antiseptic applications. It should, however, be remembered that any stimulant application may over-act, and by hurrying on the inflammation beyond that requisite for the ulcerative severation of textures, would cause the gangrene to spread. The line of separation having formed, the detachment of slough has yet to take place. During this period, its extraction prematurely would be attended with hæmorrhage, perhaps considerable. Nature may be aided gently, from time to time, by slight manipulative interference, here and there.

Finally, the removal of slough is an obvious indication which can hardly be overlooked. Dead soft textures are easily withdrawn by the finger or forceps, a sequestrum will require to be extracted from the encompassing sheath of new bone.

The healing of soft textures, subsequently, is by granulation; and the treatment that for a simple healing ulcer.

Thus ends the local treatment of inflammation, in its consequences, productively and destructively.

The treatment of the concomitant *constitutional* disorders,—hectic fever, arising from suppuration, and the typhoid fever arising from gangrene; is represented by those constitutional remedial measures which come into use as the inflammatory fever declining, is succeeded by general weakness and excitement. Stimulants and tonics on the one hand, with opium; and a nutritious diet, constitute the resources referred to.

*Pyæmia*, also, is amenable to this plan of treatment, if, indeed, it be subject to any remedial measures.

#### VARIETIES OF INFLAMMATION.

The excess or the defect, or it may be, the peculiar character, of one or more of the constituent elements of inflammation, gives rise to corresponding varieties. The principal are as follow:—*sthenic* and *asthenic*; acute, subacute, and chronic; phlegmonous; congestive; erysipelatous; diphtheritic or pellicular; hæmorrhagic; and certain specific inflammations; as the scrofulous, the gouty, and rheumatic, the syphilitic and the gonorrhæal.

The *sthenic* and *asthenic* varieties of inflammation, observes Dr. C. J. B. Williams, are referable to a difference in the strength and irritability of the heart and arteries, and in the quality and quantity of the blood which they propel. *Sthenic* inflammation is marked by a strong, hard pulse, high fever, very fibrinous blood, a full and active development of the chief symptoms of inflammation, and a tendency to the effusion of the more plastic products. Patients affected with *sthenic* inflammation require and bear more antiphlogistic treatment than others; and if used in time, such treatment is commonly very successful, for this form of disorder occurs in subjects of the most robust constitution, in whom therefore the effects of disease are most readily shaken off. *Asthenic* inflammation occurs in persons, the tone and real strength of whose vascular system is low, and whose blood, generally speaking, is poor. The pulse is not always affected; but when it is so, it is in frequency rather

than in strength or firmness; the fever, if there be any, is of a slight, remittent, or low character. The products are either scanty, or of a cacoplastic or aplastic nature; or the effusion may be chiefly serous, the inflammation differing little from flux and dropsy.

*Acute, subacute, and chronic* inflammation properly relate to its duration, but these terms are often used as synonymous with sthenic and asthenic. Acute inflammation may be, and commonly is, sthenic, but its distinctive character is, that it tends to a speedy termination of some kind or other. It may end in resolution, effusion, suppuration, or gangrene, in a period varying from a few days to three weeks. An inflammation lasting above the latter period is termed subacute, and if protracted beyond six weeks is properly called chronic. The latter is commonly asthenic, though it sometimes presents a good deal of the sthenic character. Acute inflammation, when at all extensive, is attended with considerable fever and constitutional disorder. With subacute inflammation the fever is less, and may even be absent. In chronic inflammation there is rarely much fever, and when present, it is of a remittent or hectic kind.

The products of acute inflammation are commonly copious and distinctive, being either free coagulable lymph or pus. Chronic inflammation results chiefly in pus-formation, or in contractile lymph-deposit; while in subacute inflammation, the products are often of intermediate nature, as purulent lymph, or curdy matter.

*Phlegmonous* inflammation is illustrated in the phlegmon or common boil of the skin. Its chief feature consists in its being abruptly circumscribed by an effusion of solid lymph, which brings the inflammation to a termination, either by suppuration, or by slow subsidence, as in blind boils. A highly fibrinous condition of the blood contributes to render inflammation phlegmonous, but this form of inflammation is commonly exhibited by cellular and parenchymatous textures. The type of phlegmonous inflammation is usually sthenic; and even when it advances to suppuration or sloughing, it defends the system against the noxious influence of the pus and dead matter. Hence, the fever is inflammatory, and the local pain, irritation, and heat, are considerable.

*Congestive* inflammation is that in which the accumulation of the blood in the vessels of the affected part, and retardation of its movement, predominate over the determination of blood. Hence it is commonly asthenic, and generally originates from causes that produce congestion, the reaction which converts this into inflammation being imperfect or partial. Its symptoms are less prominent than those of more active inflammation, and partake more of the character of congestion. There may be little pain, heat, or fever; but the redness, where visible, is more marked and deeper than usual, and if the affected organ be very vascular, as the liver, lungs, and kidneys, the swelling may be considerable. Congestive inflammation is usually subacute or chronic, not tending to speedy results; but a kind of flux or dropsy may occur early, as happens from congestion. The solid effusion ensuing is generally cacoplastic; thence the consolidations or indurations resulting, are often of a dense indolent kind, tending to contract or to degenerate still further into aplastic matter. Inflammation of the lung supervening on disease of the heart, on bronchitis, and on asphyxia, is generally congestive; and so is inflammation of the liver, as arising from any cause.

*Erythematic* or *erysipelatous* inflammation contrasts with phlegmonous in its tendency to spread, owing to its not being attended with the effusion of plastic lymph. In its severe form, it is accompanied by much redness, pain or smarting, heat and swelling; the effusion is chiefly serous or sero-purulent, and often raises the cuticle in blisters. It may terminate in resolution; but in its worst form, it terminates in diffused suppuration, sloughing, or gangrene. The fever is asthenic, or even typhoid.

*Diphtheritic* or *pellicular* inflammation of mucous membranes is somewhat allied to the erysipelatous, being diffused and spreading, generally asthenic, and accompanied with a low kind of fever. But it is attended with more soreness than pain, little swelling, and a deep redness, which is early obscured by a characteristic film of grayish or dirty-white albuminous matter, exuded on the inflamed surface. Patches of this kind often occur on the tonsils in sore throat, resembling sloughs. In scarlatina sometimes, diphtheritic inflammation affects the whole throat, and extends even to the trachea and bronchi, and into the mouth and gullet. The films of lymph effused are often foetid, apparently from incipient decomposition.

*Hæmorrhagic* inflammation is attended with effusion or extravasation of blood, in a greater or less degree. It occurs in subjects, scorbutic or affected with purpura, and in connexion with disease of the liver or kidneys. Thus, Dr. C. J. B. Williams has met with several instances of hæmorrhagic pleurisy and pericarditis in conjunction with cirrhosis of the liver, and Bright's disease of the kidney.

The *specific* inflammations will be fully described under their different designations, among Blood-diseases.

TREATMENT.—The treatment of the leading varieties of Inflammation is sufficiently indicated in the general course of treatment relative to Inflammation.

## CHAPTER II.

### TUMOURS OR MORBID GROWTHS.

MORBID Growths present certain general characteristics, in respect to their structure and vital endowments, which may be advantageously noticed, before describing the various species of growths.

1. In common with all other Morbid Products, Morbid Growths are products supplemental, in the sense of being additional, to the parts of the body in which they occur.

2. In their textural structure, and in their physical properties, Growths, generally resemble the various healthy tissues, in which they severally originate. There is a structural homology or at least analogy between the two; and their structural elements are similar if not identical.

But, Growths, in common with other organized Morbid Products, do not generally attain to the same state of textural development as healthy tissues; they so far represent structural retrogressions of the normal tissues to various rudimentary conditions, by arrests of development of their structural elements. [P. p. 93.]

In their degree or grade of organization, Growths represent states of

textural structure, at least as highly developed as the False tissues produced in the Reparation of Injuries or resulting from Inflammation; yet Growths are sometimes regarded as still further deviations from the organization of normal or healthy tissues.

3. A Growth generally presents a well-defined boundary, often a distinct capsule, by which the included structure can be readily distinguished circumferentially from adjoining textures.

By virtue of their structural homology or resemblance to healthy tissues, Growths may perhaps be regarded as hypertrophies or over-growths, but as discontinuous from the surrounding tissues; while, by the latter character, they are distinguished from out-growths or hypertrophies continuous with the adjoining tissues—*e. g.*, out-growing portions of the thyroid and prostate glands.

4. The vital power of Growths is peculiar, and exhibits their essentially morbid character. They possess the inherent power of reproducing their own structural elements, when adequately supplied with blood or plasma as the nutritive material suitable for their production. Hence, I would designate Morbid Growths, products of Reproductive Nutrition. They thus increase and multiply. But, another vital characteristic is this; they apparently fulfil no useful purpose in the animal economy.

"It is not," observes Mr. Paget, "in the likeness or in the unlikeness to the natural tissues that we can express the true nature of Tumours, it is not enough to consider their anatomy, their physiology also must be studied; as dead masses, or as Growths achieved, they may be called like, or unlike, the rest of a part; but as things growing, they are all unlike it. It is, therefore, not enough to think of them as hypertrophies or over-growths; they must be considered as parts overgrowing, and as overgrowing with appearance of inherent power, irrespective of the growing or maintenance of the rest of the body, discordant from its normal type, and with no seeming purpose."

Such are the general structural characters, and such the general vital endowments of Growths, or Tumours.

But the vital changes of certain Growths contrast remarkably with the progress of others.

Some appear to exercise a merely local and mechanical influence; their pathological significance is limited to surrounding parts, which are variously pressed, obstructed, and, possibly, obliterated by absorption. Inflammation, suppuration, and ulceration occasionally occur in parts around, owing to pressure of the tumour, and thus a pendulous growth, more especially, may protrude. Otherwise, the healthy mechanism only of the part becomes impaired by these *localized* Growths.

Moreover, when completely extirpated, as by the surgical operation of excision, they never return. Other Growths are localized, but they are also *recurring*; returning *in situ*, even again and again, when apparently completely extirpated. And yet other Growths are recurring but not localized; they gradually pervade surrounding tissues, and affect neighbouring lymphatic vessels and glands; they are prone to undergo ulceration, and by extension of this process thus destroy adjacent parts. They propagate also in different, and distant regions of the body, and grow in succession and with increasing rapidity. Growths having these vital characters, are aptly denominated *infiltrating* (Walshe) or *malignant*,—a less expressive term; while all other Growths being distinguished by the negation of this generic attribute, are non-infiltrating, or innocent comparatively speaking.

According to the foregoing distinctions, Morbid Growths may be classified as follows:—

Localized Growths (non-infiltrating).

Cysts.

Simple or Barren.

Serous. Sanguineous. Synovial.

Mucous. Oily. Colloid. Seminal.

Compound or Proliferous.

Cystigerous. Glandular. Cutaneous. Dentigerous.

Cystic Tumours.

Fatty Tumour.

Steatoma.

Fibro-cellular Tumour.

Painful Sub-cutaneous Tubercle. Neuroma.

Fibrous Tumour.

Fibro-calcareous. Fibro-cystic.

*Recurring Varieties.* { Fibro-nucleated  
Recurring Fibroid.

Cartilaginous Tumour. (Enchondroma.)

Varieties.

*Recurring Varieties.* { Myeloid. (Paget, or  
Fibro-plastic. Lebert.)

Vascular or Erectile Tumours.

Aneurism by Anastomosis.

Osseous Tumours.

Glandular Tumours.

Infiltrating Growths.

Cancer.

Encephaloid. Varieties.—Villous. Melanotic. Fungus Hæmatodes.

Scirrhus. Varieties.—Osteoid.

Colloid. Varieties.

Cystic Cancers.

Epithelial Cancer. Varieties.

*General Indications of Treatment.*—In accordance with the general pathology of Morbid Growths, and their relations to the developmental anatomy of healthy Tissues, certain general indications of treatment are deducible.

1. To reduce the structural condition to a lower degree of retrogression,—by degeneration or by disintegration, in order to facilitate absorption of the Tumour. Medicinal agents, and local appliances, *e.g.*, stimulating applications, compression, may fulfil this indication.

2. To superinduce some other morbid process, *in situ*, for the direct suppression of the Growth, and its obliteration or destruction as a Tumour. Inflammation, or Sloughing; by stimulant injections, setons, caustics, congelation, may fulfil this indication.

3. To remove the Tumour, as such, mechanically, by surgical operation; puncture, enucleation, ligature, excision, amputation.

**SPECIAL TUMOURS.**—Morbid Growths are severally distinguished by differences or peculiarities, in respect to their structural condition, and physical characters of shape, size, weight, consistence, colour, situation, and number produced; and by their vital history of origin, including,

hereditary predisposition and relations to age and sex; causes—constitutional and local; course, and consequences. In other words, Growths have differences of character—pathologico-anatomical, physiological and pathological, in regard to species. These differences I proceed to describe, and to consider in the diagnosis, etiology, and prognosis, of the various kinds of Tumours, as arranged in the foregoing table. The special Treatment of each will also be described, in illustration of the general indications already enunciated.

CYSTS, and CYSTIC TUMOURS.—*Structural Condition*.—This is very varied. (1) CYSTS.

FIG. 10.\*

Some contain fluid unorganized secretions, and are spoken of as *simple*, or more correctly, *barren* cysts.

FIG. 11.†

"Essentially, this species of growth," observes Paget, is "a cyst, sac, or bag, filled with some substance which may be regarded as entirely, or for the most part, its product, whether as a secretion, or as an endogenous growth." This cyst (fig. 10), sac, or bag, is either solitary, or frequently aggregated with others; and each may be free and moveable, or imbedded in the substance of some other growth, thus forming a "cystic tumour." But the contents of the cyst or cysts are the chief features of distinction.

Others contain organized, endogenous growths, and these are denominated *compound*, or more appropriately, *proliferous* cysts. (Fig. 11.) But the simple sac is the type, from which the proliferous cyst may be regarded as a departure to a more complex condition; and between the former in its simplest condition of development, and the latter in its most anomalous condition, each intermediate variety may be distinguished by the contents of the cysts, and the whole arranged in a tolerably even series of progressive organization.

\* A simple cyst in the broad ligament of the uterus, with very vascular walls. *a*, new vessels; *b*, broad ligament. 30 diam. (Wedt.)

† Proliferous cyst in a mammary gland.—A vascular growth is seen attached to part of the inner surface of the cyst. Below, is a smaller cyst nearly filled with a similar growth. Mus. St. Bartholomew's Hospital. Three-fourths the natural size. (Paget.)

*Simple Cysts.*—A cyst is formed of fibro-cellular tissue, but without an epithelial lining. This is present in the more finished cysts, and is usually the tessellated variety of epithelium. A more perfect secreting surface is thus prepared, and the varieties of simple cysts take their names from the nature of their secretions—their contents. Thus we recognise the *serous, sanguineous, synovial, mucous, oily, colloid, and seminal* cysts.

These barren cysts may be found in almost any part of the body—and to this subject I shall have occasion again to refer in connexion with the origin of cysts—but the seminal cyst has, so far as I am aware, been found exclusively attached to the spermatic cord, and by virtue of the spermatorrhœa which it contains, may be regarded as on the verge of that higher organization which characterizes the proliferous cyst.

*Proliferous Cysts.*—The organized growths within a proliferous cyst are sometimes simple cells, detached, or pedunculated and attached to the interior of the cyst whence they have sprung. Thus are formed the common *cystigerous* ovarian tumours. Occasionally the sub-cysts are found imbedded in the walls of the parent-cyst, or even projecting from its external surface, so as almost to appear of exogenous formation. This mode of cyst-formation is, I think, illustrated by inference from Dr. Mettenheimer's observations on the structure of the common hydatid mole, or cystic disease of the chorion; but for the details of this supposed process the student is referred to Mr. Paget's Lectures.

*Glandular proliferous* cysts are so named from their containing some kind of organized substance or substances, the structure of which resembles some kind of healthy gland-tissue, and for the most part that in which the cysts are imbedded. The thyroid and mammary glands, and perhaps the prostate and labial glands, are the chosen seats of this species of cyst. But a glanduliferous cyst may be developed without any connexion with a secreting gland. A tumour of this kind was removed by Mr. Paget from beneath the gracilis and adductor longus muscles of a woman twenty-five years old. The patient remained well at the end of more than three years afterwards.\* A similar case and operation occurred to Mr. Lawrence.

*Cutaneous* proliferous cysts are so called from their structure consisting of, or containing skin or its remains, with hair, or other forms of epidermic tissue, and fat. These cysts are not necessarily confined to the skin, as sebaceous and atheromatous tumours or wens, but are more commonly found in ovarian tumours; and, very rarely, in the testicle, lung, kidney, bladder, sublingual tissue, and within the skull. Teeth may also be discovered within capsules in abnormal situations, as in ovarian tumours, and the jaws; and such capsules have received the name of *dentigerous* proliferous cysts.

*Diagnosis.*—The distinctive characters of cysts are chiefly physical; their diagnosis from all other tumours being an application of pathological anatomy, through the medium of Physical Signs. [P. p. 224.]

A *simple* or barren cyst, with its fluid contents, necessarily implies a circumscribed and fluctuating tumour, or the resistance only of fluid pressure. Such are cysts,—serous, sanguineous, enlarged synovial bursæ, adventitious ganglia, often seen on the back of the wrist, mucous cysts,—*e.g.*, surcharged Nabothian follicles about the neck of the uterus, or distended Cowper's glands just within the orifice of the vagina, the less

\* Op. cit., vol. ii. p. 74.

fatty cysts,—*e.g.*, certain wens, and seminal cysts in connexion with the spermatic cord—encysted hydroceles. A collection of such cysts presents similar characters; the resistance of the circumscribed fluctuation varying in degree, from that of the most fluid, to that of the most solid-feeling thick fluid; as grumous blood, synovia, mucus, or the butter-like consistence of sebaceous cysts.

Subject to these original deviations, the typical condition of the cystic-growth is that of one or more membranous bags, filled with some kind of fluid; and, as such, its physical characters supply a complete diagnosis, both in respect of exactitude and earliness. An equivocal diagnosis can be determined by puncturing the supposed cyst with a grooved needle or with a fine trocar and canula, and examining its contents, simply by inspection, or under the microscope.

Other conditions—not deviations—are exceptional and subsequent productions:—

The *proliferous* development of a solid growth within a parent-cyst, is an occasional event; especially observed in sero-cystic disease of the breast, and in cystic bronchocele. A tumour, originally fluid and fluctuating, is thus converted into an unbroken solid mass; but during this transitional change, the growth, not yet completely filling the cyst or cysts, is immersed in fluid, so that the whole feels a mixed tumour—partly fluid, partly solid.

Ultimately, if one of the cysts should burst from over-distension, or if it be artificially laid open, the growth within, no longer restrained, increases, and protruding in the form of a fungus, gives to the tumour a new and characteristic appearance.

*Varieties.*—A thickened cyst simulates the characters of other tumours. It may resemble a chronic abscess—*i.e.*, without the pain, heat, and redness of inflammation, only presenting swelling with fluctuation. But a pus-cyst, so to speak, is more blended with surrounding tissues,—it is less circumscribed than a cyst which has merely become thickened. Or, an ordinary cyst is sometimes actually converted into a painless chronic abscess. Their diagnosis is then comparatively unimportant. This also is an occasional and subsequent condition, and one, therefore, not affecting the exactitude and earliness of the diagnosis by physical characters. The sufficiency of the physical method still prevails.

(2) CYSTIC-TUMOUR.—A cyst or cysts within the substance of a solid tumour—renders the diagnosis more obscure; but its equivocal character varies with the particular kind of tumour and the thickness of the intervening substance. Cysts are, occasionally, set in the substance of a fibrous, fatty, or cartilaginous tumour, and perhaps no kind of tumour is exempt.

The depth of integuments, underneath which a cyst may be situated, will more completely conceal its true character.

Apart, however, from exceptional and secondary conditions, the physical signs of cysts are constant. A circumscribed boundary, and fluid resistance, in some degree, to the touch, invariably accompany and announce the presence of a cyst or collection of cysts. These characters are also peculiar;—they point to no other kind of tumour or swelling, except in the cases adverted to. Moreover, they are readily perceived by clinical examination.

*Situation.*—Cystic growths—originating from the erring development of cells or nuclei—may occur in any texture or organ, but most fre-

quently in the kidney, thyroid gland, mammary gland, choroid plexus, chorion; in the neck, gums, about the sheaths of tendons at the wrist,—forming ganglions; and about the epididymis, as seminal cysts, encysted hydroceles or hydroceles of the spermatic cord. (Paget.)

Cysts having this origin are single, or numerous, in the same organ or part.

*Origin.*—Of Simple or barren cysts: the serous date from birth or earliest childhood, as by transformations of *nævi*; or from puberty or later life, as an ovarian tumour by enlargement of Graafian vesicles; or from perhaps still later life, as mammary cysts which begin during or after the time of natural degeneracy of the milk-glands. Of Proliferous cysts: the cutaneous which occur in or near the orbit, are congenital; whereas those which, as wens, occur in the scalp, are not congenital. They are, however, hereditary, though unconnected with any constitutional tendency.

*Cyst-formation*, whether barren or proliferous.—Three modes of production are tolerably well established; but no accurate classification of these growths can be determined upon this ground of distinction. Cyst-formation is as follows;—

Firstly.—By the dilatation and coalescence of the spaces in cellular tissue, a rude cyst is formed, and afterwards finished off on its internal surface, which becomes smooth, and perhaps lined with epithelium. Thus are formed certain adventitious bursæ—*e.g.*, the little sac which Hunter first pointed out underneath the skin of an old corn.

The simple cyst fashioned from areolar tissue may acquire a proliferous power, as witnessed occasionally in adventitious bursæ, from the inner surface of which pendulous little polypi sometimes grow.

Secondly.—By the dilatation and distension of certain natural cavities. Of this kind of cyst are those sacculated enlargements of the lactiferous tubes, filled with milk or serum, which Sir B. Brodie first described as sero-cystic conditions of the mammary gland. But this disease is perhaps more usually due to another mode of cyst-formation, which I shall describe presently. The mode of production now referred to may give rise to cysts in many parts of the body. For example, natural bursæ sometimes enlarge, and become distended with synovia. The bursæ betwixt the skin and patella thus enlarged, and known as “housemaid’s knee,” is a familiar example. Mucous cysts, by enlargement of the Nabothian gland-follicles about the cervix uteri, or of Cowper’s glands in the female, situated just within the vagina, are further illustrations of cyst-formation by dilatation and distension of a natural cavity with its own fluid. Fat-cysts are produced in this way, out of the sebaceous and hair follicles, forming common wens. Graafian vesicles by overgrowth, are evolved into ovarian tumours. I may here notice certain rare kinds of sanguineous cysts, which, from a case related by Mr. Paget, appear as he says, to be “dilated portions of blood-vessels shut off from the main streams.” Of sanguineous cysts thus formed, one was removed by Mr. Lloyd some years since from a man’s thigh. It lay in the course of the saphena vein, but neither that nor any other considerable vein was divided in the operation, or could be traced into the cyst. This cyst was of spherical form, about an inch and a half in diameter, and completely closed; its walls were tough and polished, on their inner surface, it was full of dark fluid blood, and its venous character was manifested by two valves, like those of veins, placed on its inner surface. On one of these a soft lobed mass, like an intracystic

growth is seated. The preparation is in the Museum of St. Bartholomew's Hospital.

This specimen teaches an important lesson; that a simple cyst formed by the expansion of a natural cavity, may become proliferous, and this truth is confirmed by the proliferous power of the lactiferous tubes when enlarged in certain cases of sero-cystic disease of the breast, and the prolific growth of cells in the parent-cysts of an ovarian cystic tumour.

Thirdly.—Besides these two modes of cyst-formation, another mode of production has been discovered, chiefly by the observations of Rokitansky,\* Frerichs,† and Mr. Simon,‡ respecting cysts of the kidney. It would appear that certain cells expand and develop themselves into larger cells, which aggregate together in "nests," each nest becoming enveloped with a thin capsule of fibro-cellular filaments, which thus forms a cyst containing cells.||

FIG. 12.||

But the erring cells themselves may each acquire sufficient size to merit the name of a cyst. The cells which naturally inhabit the villi of the chorion, according to Dr. Mettenheimer,¶ occasionally enlarge into cysts, and form the hydatid mole. From erring cells are sometimes produced serous cysts in the neck, in the thyroid body, in the gums, in the mammary gland, and a cystic condition of the choroid plexus. By this mode of origin, also, may be evolved certain sanguineous cysts,—*e.g.*, in the neck; certain adventitious synovial bursæ,—*e.g.*, ganglions formed in connexion with the sheaths of tendons; and certain seminal cysts. (Paget.)

‡ On Subacute Inflammation of the Kidney: Med.-Chir. Trans., vol. iii.

¶ Proliferous cyst-formations from the cortical substance of the kidney, as a sequel to Bright's disease.—*a*, the fibrous sheath in progress of development out of *d*, the elongated and caudate nuclei coursing around the parent-cyst or aggregation of parent-cysts. They eventually break up into the requisite fibres. *c* is to represent the point-molecule, within an amorphous blastema, out of which the nuclei (*b*) form. They are at first spherical, afterwards elongated, and ultimately broken into fibrillation. This constitutes the "alveolar type or arrangement." 90 diam. (Rokitansky.)

¶ Müller's Archiv, 1850, H. v. p. 417.

A surprising proliferous power is frequently manifested by cysts derived from erring cells, of which some instances of cystic diseases of the breast and other glands are probably illustrations. Associated with this power of growth and development, is the well-known fact, that proliferous cysts frequently recur after, as it would appear, the complete extirpation of the original cyst. Mr. Paget relates a remarkable case of this kind, recorded by M. Lesauvages.\* The patient was sixty-three years old. The first tumour of the breast, of great size, was extirpated in February, 1832; a second appeared, and was removed before the healing of the first wound; a third in May; a fourth in September of the same year; a fifth sprang up, and was removed in February, 1833; a sixth in the ensuing May; by a seventh operation, in June of the same year, three tumours were again excised; but from the same spot two more arose, which grew rapidly, and the patient died.

*Course.*—The vital career of cysts, and cystic tumours, is sufficiently indicated by the proliferous changes which cysts, originally barren, may undergo, and their issue, in the protrusion perhaps of the intra-cystic growth. The rate of growth of cysts, and the probability of their recurrence, when removed, or apparently obliterated, vary considerably.

Thus, of Simple or barren cysts; the serous and sanguineous, observe no definite rule of increase, and neither, *per se*, are likely to return. A mucous cyst is more difficult to obliterate, and long after apparent cure, may fill again. Of Proliferous cysts; the cystigerous may be slow growing, as an ovarian tumour, and not liable to recurrence, so also cutaneous cysts—as scalp wens; but cysts proliferous with vascular growths, may grow rapidly, as in the mammary gland, and very frequently return, even repeatedly.

*Treatment.*—Cysts, and Cystic Tumours are amenable to treatment, in accordance with the general indications, 1, 2, and 3. *Simple* or Barren Cysts, containing unorganized secretions of various degrees of fluid consistence, may be effectually reduced by absorption, destroyed, or removed, by one or other of the following modes of treatment:—

Stimulating applications, as the compound tincture of iodine, may induce absorption of the contents of the cyst; and if no re-secretion ensues, a cure will thus be effected. Puncturing the cyst, and drawing off its contents, followed by compression by means of a pad of lint and bandage; is also a curative proceeding of at least a temporary character. But the cyst is apt to fill again, eventually. By this treatment, I succeeded for some time, in controlling two large cysts deeply situated, one beneath the muscles of the calf, the other deep in the popliteal space. The diagnosis also, in these cases, was determined by the preparatory puncture. Puncture, and a stimulant injection, or the introduction of a seton; may succeed in obliterating the cyst by adhesion of its interior, or destroying it by sloughing, and in either way effecting a cure.

Excision of the cyst, is a procedure available when other resources have failed, or more advantageously in the first instance, before the textures have been tampered with by any other treatment. A cyst may have become converted into a painless chronic abscess. I once removed a large cyst, in this condition, from beneath the tensor-vaginæ and sartorius muscles, by an incision eight inches long. The man made a good recovery. [P. p. 233.] Complete excision is rarely necessary to ensure

\* Archiv. Gén. de Médecine, Février, 1844, p. 186.

the non-recurrence of any simple cyst; a small portion left after operation, will granulate and cicatrize. But a cluster of cysts must be removed entirely; otherwise, any one remaining will afterwards continue to grow. Thus, the whole mammary gland, if beset with cysts, must be sacrificed.

*Proliferous Cysts.*—Excision is the only sure and safe mode of treatment; removal of the cyst or cysts entirely, by the knife, being necessary to overcome the productiveness of any such cyst. Cystigerous, and glandular, proliferous cysts, the latter especially, render this proceeding the more necessary. Cutaneous proliferous cysts also are more properly excised. The common scalp-wen, for example, in most instances; and the operation in this case is very readily accomplished. An incision having been made extending down through the cyst, either half can be seized with forceps and easily turned off its bed, the cellular connexion offering very slight resistance. Erysipelas is apt to follow this simple operation, in old or debilitated subjects. It may, therefore, be advisable in such cases, to remove the contents of the cyst by puncture, or even to destroy the cyst by sloughing. If the former mode of treatment be adopted; the introduction of a probe through the small black point existing in most cases, will permit the contents to be squeezed out of the cyst, which may then be made to heal from the bottom, by the substitution of a few threads as a seton. Or if it be desirable to induce sloughing of the cyst, this can be effected by introducing a stick of caustic potash, and turning it about a few times, or by pencilling the skin over the cyst. In either way the cyst is laid open when the slough separates, and heals from within. Nitric acid and other powerful irritants are useful for the same purpose.

*FATTY TUMOUR.*—*Structural Condition and Diagnostic Characters.*—This growth is of soft doughy consistence, defined or circumscribed, deeply and largely lobulated (Fig. 13), and freely moveable; sometimes shifting from its original locality owing to the looseness of its connexion; often attaining to a large size and great weight, even to fifty pounds; usually

FIG. 13.\*

FIG. 14.†

subcutaneous, and probably situated somewhere about the trunk, posteriorly, and solitary. It has the composition and general structure of ordinary fat—*i.e.*, fat-cells (Fig. 14), collected together, and imbedded in a fibrous mesh-work, more or less abundant, and resembling condensed cellular texture; this, however, is continuous with a thin fibro-cellular

\* Fatty tumour, removed from under the tongue; half size. (Liston.)

† Structure of a fibro-fatty tumour. *a.* Isolated cells, showing stellate crystals of margaric acid. (Bennett.)

capsule enclosing the tumour; prolongations of which, penetrating the mass, separate it into lobes, while, externally, the whole investment is loosely connected with surrounding parts. Blood-vessels, collected mostly at one point of the tumour, pass into its substance from the cellular capsule.

*Varieties.*—Occasionally, the cellular capsule is thick, dense, and fibrous. Its prolongations may also become fibrous and firm. The whole substance of such a tumour is hard and comparatively immovable, and although still circumscribed and lobulated, resembles a fibrous tumour. The *lardaceous* variety is of this description. Hard fibrous knots, as of the fibro-cellular stroma, or even bony nodules, can, occasionally, be felt within a tumour, otherwise fatty. Or the mass may be, or become, softer than usual. Oleaginous fat, with but slight fibro-cellular partitions, presents the characters of a bag or cyst of fluid, and gives out the physical signs of a fluid encysted tumour. True cysts are, occasionally, developed in a tumour otherwise fatty; thus giving the consistence of roundish elastic bags of fluid set in a doughy substance. Still more rarely, suppuration occurs, centrally perhaps, within a fatty tumour, and forming a chronic abscess, simulates the character of a cyst.

Lastly, the characters of any such tumour, purely fat or mixed, may be obscured by the depth of integuments beneath which it lies buried.

But all these conditions are exceptional, and, excluding that of the occasional depth of the tumour, they are subsequent conditions also. Neither, therefore, will scarcely affect the exactitude and the earliness of diagnosis, by physical signs; the ordinary physical characters of fatty tumour being generally present, and exclusively indicating this kind of growth and no other morbid condition. *Steatoma*—a lard or suet-like variety of fatty tumour—is liable to occur in whatever part of the body this growth makes its appearance; but steatoma has been found in some parts more especially; among them, in the mesentery, testicle, and mediastinum. (Walshe.)

Fatty tumour is usually a solitary growth; but in exceptional cases, several may co-exist from two or three, up to as many as a hundred, or more.

*Situation.*—Fatty tumour most commonly occurs in the subcutaneous adipose texture, especially of those parts where fat normally abounds in the healthy state, and is liable to accumulate; as about the trunk—*e.g.*, on the back, neck, and shoulder; also over the buttock, and the thigh; between the peritoneum and abdominal walls, escaping from which by the abdominal rings, it forms fatty hernia, so called. (Walshe.)

This kind of tumour occurs more rarely in synovial sacs, especially that of the knee-joint, the "*lipoma arborescens*" of Müller. It sometimes forms where fat is normally scanty, as beneath the hairy scalp; or, where fat is normally absent; as in the sub-mucous cellular tissue of the stomach, the intestine, the bronchi; in the sub-serous cellular tissue of the pleura or dura-mater, and beneath the investing membranes of the ventricles. Also in the substance of organs; especially in the lungs, liver, kidneys, and in bone "affected with osteoporosis and eccentric atrophy." (Rokitansky.) Between the corpora albicantia and optic nerve, in one case. (Müller.)\* A fatty tumour, the size of a mushroom, was found between the arachnoid and dura mater, on the level of the fourth lumbar

\* On Cancer, p. 153.

vertebra. (Albers.)\* One as large as a walnut, in the walls of the vena portæ. (Andral.)†

*Origin.*—Fatty tumour is very rare in children, but not unfrequently begins in youth, though, growing slowly, it may be overlooked for many years; it may begin to grow at any later age, but very seldom appears first in old age. This kind of tumour scarcely ever seems to be hereditary. Sometimes it has so appeared after fever or some general illness, as to seem due to a constitutional cause. It is sometimes referable to local causes, as a blow, or, more commonly, frequent friction, as by a strap or band over the skin. But in the majority of cases, no good cause whatever can be assigned.

*Course.*—The influence of a fatty tumour is purely local and mechanical. The rate of growth is generally very slow, sometimes fitful, very rarely rapid. It does not return, even when partially removed. It is not liable to ulcerate, but I have seen ulceration of the skin, apparently resulting from weight and friction, in the most dependent part of a pendulous fatty tumour in the thigh.

*Treatment.*—Absorption of a fatty tumour is perhaps possible, under the influence of medicinal treatment. Thus, this kind of growth is said to disappear occasionally under the influence of liquor potassæ, administered in half-drachm doses, gradually increased to a drachm, and continued for a month or more. In one case, the tumour was sensibly diminished in size by this mode of treatment, which was originally tried by Sir B. Brodie.

Excision, as a rule, is the only successful treatment. It is rendered necessary by the large size to which a fatty tumour generally attains; and especially when the mass is so placed—which, however, is not generally the case—that by its further enlargement, it would encroach on important parts adjacent, thereby rendering the operation eventually difficult or impracticable. The freedom with which a fatty tumour shifts its place, owing to the loose cellular connexions of its thin dry capsule, is an additional reason for timely performance of the operation. I have thus had occasion to remove a fatty tumour from the cheek, from the shoulder overhanging the axilla, and from other situations. The operation itself, although perhaps extensive, is easily performed.

Dissection, even among parts of anatomical importance, is scarcely requisite. The lobulated mass rolls out of its bed or is easily detached, until some corner appears where the nutrient vessels enter. Hæmorrhage is inconsiderable, but when these vessels are divided, a ligature or two may be needed. Any small portion of the tumour left behind is immaterial, it ceases to grow. The portion of skin to be removed is not so extensive as would at first sight appear necessary. Any small portion spoilt by pressure and any superfluous portion, may be included in the excision; but the remaining integument will retract and pucker up, after the operation.

**FIBRO-CELLULAR TUMOUR.**—This growth is distinguished from polypus, mucous or cutaneous, chiefly by its relation to the adjoining texture. Both are over-growths; but, while polypus is merely an out-growth of fibro-cellular tissue, the same structure, as a tumour, is distinctly isolated by a capsular investment.

*Structural Condition, and Diagnostic Characters.*—The mass, thus

\* Pathologie, B. ii. s. 189.

† Anat. Path. ii. 412.

detached, is roundish, and of tolerably regular outline, usually deeply and largely lobed. Its chief physical character is a remarkably elastic tension, due to the structural resemblance of this tumour to dropsical cellular tissue, circumscribed. It may grow to great size and weight, perhaps forty pounds. Section shows a yellow surface, marked with white lines, which have an undulatory direction across the tumour, and may divide its substance into distinct lobes.

The yellow substance, the white bands, and the capsule, alike consist of fibro-cellular tissue, more condensed in the latter portions; but the whole is remarkably succulent, being infiltrated with a serous fluid, which exudes plentifully and continues to ooze from the cut surface.

*Situation.*—Fibro-cellular tumour occurs most frequently in the scrotum, labium, or tissues by the side of the vagina; or in the deep-seated inter-muscular spaces in the thigh and arm.

As out-growths, some proceed from, and are connected with, the mucous membranes, forming polypi—*e.g.*, in the nasal passages, very rarely in the antrum; in the external auditory meatus; in the uterus, and urinary bladder. (Paget.) As cutaneous out-growths, they appear on the scrotum, prepuce, nymphæ, clitoris and its prepuce. In one instance, a fibro-cellular out-growth—which I examined with the microscope after its removal from the clitoris—was the size and shape of a large cocoa-nut. It weighed thirty ounces.

Fibro-cellular tumour, not out-growth, is usually solitary.

*Origin.*—This kind of growth may begin at any period of life, but most rarely before adult age, and most frequently at middle age or later in life. It is so seldom referable to inheritance, any general disease or to violence, that any such relation would appear to be only a coincidence.

The tissue of which, together with the serous fluid, this tumour consists, represents an immature state of the normal fibro-cellular tissue. With many well-developed filaments, there are more abundant nuclei and cells, forming fibres—fibro-cellular tissue, in various stages of development. Yellow elastic tissue is very rarely present, unlike its frequency in ordinary connective tissue. Analogous, as the texture of this tumour is to ordinary fibro-cellular tissue; it is, nevertheless, of rare occurrence, compared with other tumours—fatty, or cartilaginous—whose component textures, respectively, are reproduced far less frequently than this tissue.

*Course.*—Portions of cartilage sometimes partially ossified, are occasionally produced in, or over, the tumour. (Paget.) Its texture may also degenerate. The rate of growth is variable; being very rapid, as much as three or four pounds a year—*e.g.*, in the scrotum; or more slowly increasing. Recurrence is very improbable, unless the tumour be unusually soft and succulent, and the fibre-cells in great proportion rudimentary.

*Treatment.*—Excision of a fibro-cellular tumour is the only effectual mode of removal. It becomes necessary owing to the increasing size of the growth. The operation cannot be accomplished with the same facility as that of a fatty tumour. Nevertheless, a thin capsule defines the lobulated mass, its connexions are not very close, and the hæmorrhage is but slight compared with the size of the tumour. I have excised such tumours without any recurrence.

The largest fibro-cellular out-growth I have yet seen,—that of the clitoris enlarged to the size of a cocoa-nut, was easily removed by a sweep of the knife through the peduncle.

**PAINFUL SUBCUTANEOUS TUMOUR, or TUBERCLE**—so named by Mr. W. Wood,\* who first described it—is a peculiar variety of fibro-cellular tumour, to which and to fibrous tumour, it is structurally allied; but peculiar, if only as distinguished by the pain, intense and paroxysmal, which commonly occurs, and which is not to be accounted for by the structure of the tumour, itself perhaps destitute of any nerve-filaments, nor by any special relation to adjacent nerves.

This painful tumour, situated in the subcutaneous cellular tissue, is barely visible; for it is beneath the skin, and scarcely projects. It is also of small size, rarely exceeding half an inch in diameter; but it can be readily felt, as a roundish body, very firm and elastic. Isolated by a capsule, this hard body is free in the subcutaneous tissue, and is, therefore, so far moveable; but it may be intimately adherent to the skin, and move with it when pressed under the finger. The superimposed skin, if adherent, has the general appearance of a cicatrix; it is slightly puckered, stretched, glistening and white, unless during a paroxysm of pain, when it may become congested and swollen, and the surrounding blood-vessels turgid.

The surface and section of this tumour are alike in colour variable; commonly yellowish; sometimes only greyish, or pure white. Its substance consists of fibro-cellular or fibrous tissue, with an abundance of nuclei intermixed; and the whole represents an immature state, or rather various immature states, of either tissue. Nerve-filaments have not been discovered. The tumour is usually solitary, as well as subcutaneous. It is thus also distinguished from Neuroma, a fibrous tumour connected with a nerve. This latter species of growth is characterized by the presence of nerve-filaments in, or spread over, the mass; and by the large number of such tumours often produced in various parts of the body, not less perhaps than 2000 having been found in one unprecedented case. (R. W. Smith.)

*Situation.*—Painful subcutaneous tumour or tubercle occurs, as its name denotes, beneath the skin; and especially in the extremities, more particularly the lower limbs, very rarely on the trunk or face. It has, I believe, been found deeply imbedded in the substance of muscle.

This tumour is solitary in nearly every instance.

*Origin.*—Painful tubercle is very rare in both early life and old age. It occurs much more commonly in the female than in the male.

*Course.*—Slow growth, and non-recurrence when removed entirely, characterize the life of this little tumour.

*Treatment.*—This variety of fibro-cellular tumour generally requires the same treatment as that growth. But excision is resorted to, and with the ready concurrence of the patient, to exterminate, so to speak, the otherwise excruciating paroxysmal pain in the tumour, rather than in consequence of any mechanical inconvenience by its size, which is always inconsiderable. The pain may perhaps be relieved, for a time, by firm pressure with a metallic ring placed on the circumferential portion of skin; but the tumour will ultimately have to be excised to obtain permanent relief from suffering. I am not aware that pain ever recurs in the cicatrix, although free excision may be advisable, as a precaution; assuredly the tumour itself never returns, when completely extirpated.

\* Edin. Med. and Surg. Journal, vol. iii., 1812.

*Neuroma* is also amenable only to excision. The nerve-filaments, enclosed in, or expanded over, this little tumour, must generally be divided. Occasionally, the tumour can be dissected out of the nerve, leaving it intact. This more conservative mode of excision is especially important in the case of a large nerve, as the sciatic. But the presence of more than one, sometimes very many, neuromata in various parts of the body, may render any operation useless.

As a palliative, in both these forms of painful tumour, the topical application of the most benumbing anodynes—*e.g.*, the tincture of aconite, is worthy of trial. I have met with instances of fixed pain limited to a spot, at the junction of the ball of the thumb and wrist, and in other situations; where great relief has been obtained by the occasional application of aconitine ointment,—one grain to a drachm of lard. The best aconitine must be used; it was prepared by Messrs. Morson, of Southampton-row, who are justly celebrated for the preparation of this and other vegetable alkaloids.

**FIBROUS TUMOUR.**—*Structural Condition and Diagnostic Characters.*—The great firmness and elasticity of this growth are peculiar; and less so, its spheroidal shape, when uninfluenced by the pressure of surrounding parts, and its occasionally lobulated character. The tumour sometimes attains a large size and weight, even seventy pounds. Its chemical basis is gelatine, but the other constituents are unknown. On section it presents a greyish colour, variously intersected by white opaque lines. It consists of the white, and perhaps the yellow or elastic fibres of ordinary fibrous tissue, which have an undulatory arrangement (fig. 15); and like that tissue, it is but scantily supplied with blood-vessels, which pass into the substance of the tumour from a fibro-cellular capsule, this investment being more apparent around those tumours which are imbedded in solid organs.

FIG. 15.\*

*Situation.*—Fibrous tumours are formed in connexion with the fibrous or fibro-cellular textures; most commonly in the substance of the uterus, or in the fibro-muscular tissue of the ligamentous reflexions of the peritoneum; in the ovaries, Fallopian tubes, or vagina; (Walshe); in the interstitial fibro-cellular tissue of nerves. Connected sometimes with bone, and—like cartilaginous tumours—formed either in its substance, or between it and the peritoneum. The jaws are most liable to this kind of growth. Connected with the dura mater, is another frequent situation. In the sub-mucous cellular tissue, “more particularly of the intestine, stomach, and œsophagus; now and then in that of the larynx;” (Rokitansky); in that of the pharynx, the nares, the frontal and sphenoidal sinuses; in the sub-peritoneal and sub-pleural tissue; (Walshe); in the subcutaneous cellular tissue, as in the lobules of ears, after piercing for ear-rings (Paget); in the mammae, testicle, thyroid gland, thymus gland; in the arterial tissue; and indeed wherever fibrous or fibro-cellular tissue is normally present or most prevalent.

\* Uterine fibrous tumour, section, like polypus, but discontinuous with the substance of the uterus. (Paget.)

Fibrous tumour is usually a solitary growth; excepting in the nerves or uterus, in either of which several may co-exist. But when in the uterus, this species of growth rarely forms in any other part at the same time. (Paget.)

*Origin.*—This tumour has perhaps no definite relation to any period of life, nor to any hereditary constitutional tendency. An apparent exception to this negation, is the uterine fibrous tumour; a fibro-muscular rather than fibrous growth, and which may have some physiological relation to the organ in connexion with which it occurs.

*Course.*—The influence of fibrous tumour is purely local and mechanical. The rate of growth is slow, as compared with that of fibro-cellular tumour; but recurrence is equally improbable.

*Varieties.*—Earthy matter or cysts may be found within the substance of this growth, and hence the terms,—fibro-calcareous and fibro-cystic, as designating these modifications. Other and more important varieties are recurring growths;—the fibro-nucleated (Bennett), and the recurring-fibroid. (Paget.) (a) The *fibro-nucleated* variety presents the external appearance and general characters of an ordinary fibrous tumour, for which it might be readily mistaken. But, the microscopic characters are those of the white fibres of fibrous tissue, mixed with numerous large oval nuclei; thus representing a developmental condition of healthy fibrous tissue. In point of course and tendency, the fibro-nucleated variety does not affect the lymphatics around, nor does it contaminate more distant parts; yet, when extirpated, it has a tendency to return, *in situ*. (b) The *recurring fibroid* variety also, in its first stage, presents the external appearance and general characters of fibrous tumour. But, in its minute structure it consists essentially of fibre-cells, cells elongated and attenuating into white fibres, mixed with nuclei; thus representing another developmental stage of healthy fibrous tissue. Not affecting parts contiguous or remote, the recurring fibroid variety has emphatically, as its name would suggest, a tendency to return, again and again, *in situ*. Moreover, in this its second stage, it successively assumes the appearance of encephaloid cancer; having now become soft, bloody, and fungoid; but retaining its former structural characters, and vital significance, which is only somewhat less than that of encephaloid cancer.

It will, therefore, be observed that the fibrous tumour, and recurring fibroid in its first stage, possess the same physical characters, conjoined with a different structure; and conversely, recurring fibroid tumour, in its first and second stages, presents dissimilar physical characters, associated with the same essential structure.

Yet the vital significance of these growths is of widely different import; ultimately approaching to that of cancer in its typical form.

Growths thus constituted, and endowed, illustrate, even more conspicuously than the fibro-nucleated variety, the diagnostic insufficiency of Physical Signs, [P. p. 224]; and the superior diagnostic value of minute Structural characters, [P. p. 243].

The practical value of this principle of Diagnosis, is to be estimated by the clinical fact, that, in all available situations, the minute structural characters of the tumours in question—and of other doubtful tumours—may be discovered by puncture with a grooved needle and direct examination of the tumour-substance with the microscope.

*Origin.*—Both the recurring varieties of fibrous tumours, usually begin between youth and middle age, very rarely either in childhood or in advanced life.

*TREATMENT. Fibrous tumour.*—Excluding this form of growth in the uterus—excision is still the only known remedy. Considering the large size to which the tumour sometimes attains, and especially, the irregular shape which it acquires by adaptation to the parts around; the operation should be performed early. It is, however, accomplished less readily than that for a fatty, or even a fibro-cellular, tumour. Yet a thin capsule defines, and but loosely attaches the tumour to surrounding parts, from which it can be easily split; and the hæmorrhage is inconsiderable, as pertaining to the tumour. In connexion with bone, the attachment is very close, and the basic portion of bone will probably have to be removed. Enucléation—or simply turning the tumour out of its bed—is available in some instances; chiefly for the removal of uterine fibrous tumours. Recurrence, after either mode of operation is very improbable.

*Recurring Fibroid, and Fibro-nucleated Tumours.*—The treatment of both these recurring varieties of fibrous tumour is governed by the same general considerations. They are not influenced by any known medicinal agents, except perhaps the first named variety of this growth. Iodide of potassium in large doses continued for several weeks, seems to have prevented the return of recurring fibroid tumour, in cases observed by Dr. Esmarch of Kiel. Excision is the only other resource. The size and often rapid growth of these tumours, are urgent considerations. The operation must be freely performed, to ensure, if possible, total extirpation of the tumour, which, however, is localized, though apt to return. Hæmorrhage may be profuse.

The probability of recurrence is uncertain. Any such tumour may be removed, apparently entirely, an indefinite number of times, and each interval may be of longer duration, even to some years apart, after repeated operations; thus prolonging life, and granting successive periods of ease. Or, as is usually the case, this history may be reversed; more rapid growth, and shorter intervals of freedom, larger operations, progressive exhaustion and death.

*CARTILAGINOUS TUMOUR.—ENCHONDROMA OF MÜLLER.*—*Structural condition and Diagnostic characters.*—This tumour presents the appearance, the chemical composition, and the structure of masses of fœtal cartilage. It is enclosed in a tough fibrous capsule, which conducts a few blood-vessels.

The surface of a cartilaginous tumour is more or less irregular and lobulated, the fibrous capsule passing in between and separating the lobes; the whole mass varying also considerably in size (Figs. 16, 17). Its substance is pulpy or more consistent, it may be hard, but elastic, crisp when cut, and a section is bluish-white, like London milk, glistening

FIG. 16.\*

\* Enchondroma of the hand. (Druitt.) The tumours are drawn too regularly round, and have not the nodulated character of the cartilaginous tumour. (F. J. G.)

and translucent. These appearances, however, vary with modifications of structure.

FIG. 17.

Two structural elements are found, the same as in ordinary cartilage; cells, and an inter-cellular substance, the latter being semi-transparent or molecular and dim,

FIG. 18.\*

but more commonly fibrous. (Fig. 18.) The cells also may be scattered or aggregated, multiform, and they resemble either mature or rudimentary cartilage-cells. Their envelope is, therefore, more or less defined, it encloses one or more nuclei, within each of which is seen a nucleolus or two. Occasionally, the nucleus appears radiated, not unlike the lacunæ and surrounding canaliculi of bone. There is, in fact, an intimate structural homology between the cartilaginous tumour and healthy cartilage, in its develop-

mental conditions; and this resemblance extends to the myeloid variety of enchondroma.

*Situation.*—Cartilaginous tumour is most frequently connected with the bones and joints; especially those of the hand—*i.e.*, phalanges and metacarpus, the corresponding bones of the foot, particularly the last phalanx of the great toe; the lower end of the femur, neighbouring end of the tibia; the humerus, sternum, ribs, ilium, and cranium. Apart from bone and cartilage, these growths may form in the parotid gland, testicle, mammary gland, lungs, and in the subcutaneous areolar tissue. (Rokitansky.)

\* Cells, and inter-cellular substance or stroma, of a cartilaginous tumour, from the phalanx of a finger. Many of the cells are only drawn in outline; some of them present double or triple contour lines; most of the nuclei are large and granular. The groups of cells are intersected by bands of tough fibrous tissue. Magnified about 400 times. (Paget.)

This kind of growth is not unfrequently solitary, excepting in connexion with the bones of the hands or feet, where several may co-exist.

*Origin.*—In connexion with bone, cartilaginous tumour begins most commonly at an early period of life; some, on the hands, in infancy, others, more often, between childhood and puberty. Their beginning in later life is, however, not very rare, even on the bones: and in other parts, they commence, usually, in full adult or middle age. Inheritance, or injury, may have some influence in the production of this tumour, particularly in connexion with bone.

*Course.*—The influence of a cartilaginous tumour is purely local and mechanical. The rate of growth is uncertain; generally slow, occasionally rapid. Recurrence is very improbable, unless in the case of a soft cartilaginous tumour.

*Varieties.*—The consistence of an ordinary cartilaginous tumour is liable to undergo remarkable changes. A species of ossification sometimes takes place, beginning either on the surface or within the substance of the tumour. Again, the whole tumour may soften and feel like a fatty growth, or a mass of colloid cancer; or ossific nodules may soften and feel like a group of cysts. Such are the most important points of apparent resemblance between the cartilaginous tumour and other growths.

*Myeloid tumour* is allied to the fibrous by virtue of one structural element, the fibre-cell, and to the ordinary cartilaginous tumour by its more abundant many-nucleated corpuscles. These corpuscles and imperfect fibres appear to be identical with those of healthy rudimentary bone. Hence, the marrow-like “myeloid” in substance, as so designated by Paget, has also been named “fibro-plastic” tumour, by Lebert, its structural elements resembling those of granulations springing from healthy bone.

The external characters of the myeloid variety of cartilaginous tumour are tolerably definite. Its surface is more or less lobulated. If enclosed within bone, its shape is uniform and spheroidal if seated on the surface of a bone, its outline is irregular, as seen in epulis. The fleshy, inelastic firmness of a myeloid growth is remarkable, although its consistence varies. On section, the surface presents a greyish-white basis colour, daubed with irregular blotches of a bright red, livid or brownish tint. This blotched appearance is unconnected with any corresponding vascularity, the supply of blood-vessels being scanty even when the tumour is most ruddy. The cut surface is also succulent, and exudes a yellowish fluid.

*Situation.*—Myeloid tumour selects bone more frequently than any other tissue. Paget has seen this growth in the mammary gland, and probably also in the neck near the thyroid gland.

*Origin.*—The tumour begins very rarely in early life, or in old age; most frequently between youth and middle age. It is seldom referable to inheritance, defective health, or injury.

*Course.*—The rate of growth is usually slow. Myeloid tumour is not apt to ulcerate or protrude like a recurrent fibroid growth; but it is liable, if not prone, to return when extirpated by the knife, thus differing essentially in its vital career from the typical form of cartilaginous tumour.

*TREATMENT.*—Cartilaginous tumour must be removed by surgical operation. But, the size to which it may grow is scarcely so much a considera-

tion, as the firm attachment of the tumour to bone, in the great majority of cases. Amputation, therefore, rather than excision is indicated. The performance of the latter operation is aided by certain circumstances. The mass, usually lobulated, is defined by a tough capsule investing the whole surface, excepting at the base of attachment. Within bone, this investment is complete. In either case, the capsule is connected to the texture around, by a dry connective tissue which can be more or less readily split up. The hæmorrhage is but slight, as occasioned by removal of the tumour itself only sparingly vascular; and the surrounding textures are singularly healthy.

Enucleation of a cartilaginous tumour from within bone, is—observes Mr. Paget—more often practicable than practised.

Recurrence need not be apprehended, otherwise than in exceptional cases.

*Myeloid tumour* admits only of free excision or amputation, and as a recurring growth is far less favourable for operation.

FIG. 19.\*

#### VASCULAR OR ERECTILE TUMOUR.—

*Structural Condition, and Diagnostic Characters.*—This tumour essentially consists of a conglomeration of blood-vessels, connected together, more or less intimately, by fibro-cellular or connective tissue, which may form an investing capsule; the whole being thus circumscribed as a distinct tumour, but of irregular shape, and perhaps lobed (Fig. 19); or, the mass not being distinctly isolated, is diffused, flattened, and shades off into the surrounding textures. The size or extent of such a mass, in either case, varies with its growth, and is subject to temporary alterations, under circumstances which will be noticed presently.

*Situation.*—This species of tumour may be deep-seated, in or among muscles, in bone, the stomach, spleen, liver, the orbit, the tongue, and indeed wherever capillary blood-vessels naturally exist and most abound. The diffused form is more frequently situated superficially, as beneath the skin, and probably involving it; constituting the common cutaneous nævus, as seen on the scalp or the face.

*Varieties.*—Three varieties of this tumour are well defined, and easily recognised when it is patent. The constituent blood-vessels are capillaries, with arterial and venous trunks proceeding respectively, to and from the mass; but either order of vessels may predominate, and constitute nearly the whole mass, apart from the connective tissue. Thus then there are the capillary, the venous, and the arterial varieties of vascular tumour.

The *first* consists almost entirely of capillaries—large, dilated, and convoluted. The *second*, almost entirely of veins or venous sinuses—

\* Section of an erectile-tumour—showing the fibrous trabecular structure, and investing capsule.—Museum of the Royal College of Surgeons, England. Drawn one-third larger than the specimen.

forming a cavernous and erectile structure. This variety of vascular tumour, was that which John Bell specially described,\* and to which he gave the name of "aneurism by anastomosis," or "Aneurism by the dilatation of anastomosing vessels.† He compared it to the erectile structure of the penis, the gills of a turkey-cock, or the substance of the spleen, placenta, or womb. The *third* variety consists almost entirely of arteries—large, tortuous, and perhaps convoluted. This is now called—"aneurism by anastomosis." (Fig. 20.) These varieties of structural condition are accompanied with corresponding peculiarities of *physical* characters, by which their diagnosis during life can be determined.

FIG. 20.

The vascular tumour is soft and compressible, but regains its former size when the congeries of vessels is left free to fill again. Its substance somewhat resembles a sponge; and if visible, as when subcutaneous or in the skin, the colour of this distended sponge plainly shows that it is full of *blood*, arterial or venous. The capillary and venous varieties are alike characterized by their circumscribed shape and soft doughy consistence, which can be moulded under the fingers; but at the same time a trembling sensation or *indistinct throbbing* is felt, if the mass for the most part be venous, and have attained some size. After compression, the tumour *slowly re-distends*, and assumes increasing size and tension during exertion, especially if sudden and violent, as running, coughing, straining, struggling; and by any obstruction to the free return of venous blood. A *bluish* tint is perceptible when the tumour is situated superficially. Lastly, if wounded, the mass collapses. The arterial variety is chiefly distinguished by its *strong* pulsations, and threatening distension, increasing

\* Principles of Surgery. Ed. by C. Bell, 1825, vol. iii. p. 328. † Ibid., p. 386.

also under any occasional excitement of the heart's action, and with the flow of arterial blood.

*Origin.*—The vascular tumour is not unfrequently a congenital growth; it may be a subsequent formation, but more frequently in childhood than in after years. The progress of growth is not generally steady, but by fits and starts; sometimes rapid, sometimes slow-growing. Very commonly—observes Paget—their increase is only proportionate to that of the rest of the body; and when full growth is attained, they also cease to grow. Not rarely they are stationary, or shrink, even while the rest of the body is growing; and this is especially likely to happen with those that are white and scar-like where the skin is involved.\*

*Course.*—The same authority also notices certain structural alterations to which the vascular tumour is subject, by degeneration or by disease.

These morbid conditions disguise the original character of the tumour, and may now mislead the diagnosis. Thus, a vascular tumour may become converted “into a soft, but tough and dry yellow-ochre or brown substance, like that of a supra-renal capsule.” Scar-like patches is another transformation, affecting the substance, or surface of the tumour, and accompanied with closure of the vessels in that portion. Acute inflammation may consolidate and cure; or, leading to ulceration, form bleeding sores, ill-disposed to heal. Either blood-clots, or phleboliths, sometimes partially consolidate; or cysts, serous or sanguineous give a more elastic feel to the mass. More rarely, this kind of growth, forms in another growth, and usurping its structure, converts part, or the whole of such growth into a vascular tumour, and acquires its character. Lastly, “it is probable also that one form of vascular tumour may be converted into another: a capillary one becoming either arterial or venous, by the excessive growth of one or other set of vessels; or an arterial one, by opposite changes, becoming either capillary or venous.”

*Treatment.*—Vascular or Erectile tumours admit of treatment in accordance with each of the three general indications pertaining to morbid growths.

(1.) Absorption, by compression, steadily maintained by means of the air-cushion and spring. Compression is most practicable and effectual when the tumour rests on bone, thus supplying counter-pressure.

(2.) Obliteration, by cauterization, or injections, for the purpose of producing sloughing or consolidation of the tumour. Either plan of treatment is most appropriate for small vascular tumours, as certain nævi. In parts where the deformity occasioned by sloughing and cicatrization are unimportant considerations; cauterization, with the strong nitric acid freely applied to the integument covering the tumour is perhaps warrantable. In parts otherwise circumstanced, as the face, the injection of some stimulant into the tumour is preferable, with the view of exciting inflammation short of sloughing, and thence consolidation of the tumour. Perchloride of iron may thus prove remedial, introduced drop by drop at different points, by means of a glass syringe, having a screw piston and a fine penetrating nozzle. Setons of silk, passed through various parts of the tumour, and allowed to remain in for some days, will, perhaps, more slowly produce the same result.

I have not had much experience in either of these, or similar modes

\* A System of Surgery, 1860. Ed. by T. Holmes, vol. i., Tumours.

of treatment. What I have done or seen has led me to avoid such applications, as useless or perilous.

(3.) Removal, by ligature or excision. The former method is appropriate for vascular tumours *larger*, and, therefore, more arterial or venous, than those which can be safely obliterated by caustics or injections, or in cases where such treatment has failed. The advantages are; less liability to hæmorrhage, and a more healthy sore when the tumour is detached. The difficulties are; to include all the vessels connected with the tumour around its base, and to completely strangle without cutting them by the ligature,—thus ensuring extirpation of the growth. But success is at least equally uncertain with regard to the treatment both by obliteration and absorption. Cessation of pulsation, a thrilling tremor in the tumour, and inability to reduce it by pressure; are signs that the operation of ligature has been effectually performed.

An erectile tumour requires, and is amenable to operative treatment, according to its size, situation, and the character of the growth.

NÆVUS.—When of small size, cutaneous, and not progressively increasing, a nævus may well be left to itself; and it may atrophy, wither, and disappear. When of large extent, although superficial, as occasionally seen on the face, presenting the appearance of a large purple patch; such nævus must be left alone, it is irremovable, albeit a great disfigurement. But, when nævus is of large size, or subcutaneous, and increasing in size, occasioning also much disfigurement; operative interference becomes necessary, and indeed urgent in proportion to the development of these characters.

*Operations for the cure of nævi* may be performed with a view either to their destruction and obliteration, or to their removal. (1) To induce adhesive inflammation in the substance of the tumour, with coagulation and permanent plugging of the erectile tissue; (2) cauterization, by the application of strong nitric acid or potassa fusa, in order to thus destroy the growth; (3) removal by excision, with the knife; or (4) by ligature, applied subcutaneously. *Adhesive inflammation*, as a means of destroying nævus, is eligible only when the tumour is of small size, and occurs in situations inaccessible for excision or ligature. Nævi situated near the eyelids, at the inner canthus, or on the tip of the nose, are thus circumstanced. Inflammatory adhesion and coagulation may be induced in various ways. By the injection of some stimulant, as perchloride of iron, by means of a screw-piston glass syringe, as used for the hypodermic injection of morphia; care being taken to throw in not more than two or three drops at one time, lest sloughing supervene, or coagulation extending into the surrounding vessels, a fatal embolism ensue from a clot entering the general circulation. Galvano-puncture is another mode of exciting coagulation, and consolidation. Subcutaneous puncture, and division of the vascular tissue, by means of a fine tenotomy knife, is also an efficient, and a safe mode of destroying the tumour, in like manner. Or, by the introduction of seton-threads, for a sufficient time, and at different parts, so as to induce inflammatory consolidation.

*Cauterization*, is eligible for the destruction of nævus, where it is small, and cutaneous; and its disfigurement is worse than the cicatricial scar resulting from the application of strong nitric acid or potassa fusa. Thus, a small "mother's mark," or an acquired vascular spot, may be touched with a glass rod dipped in the acid, or lightly pointed with a stick of the caustic.

*Excision* may be resorted to for the removal of large nævus, but this method will be appropriate especially when the growth is distinctly encapsuled, and can be dissected or shelled out.

*Ligature*, applied subcutaneously, is the other method of removal which must be had recourse to, in all other conditions of nævus, when of large size, not encapsuled, but connected with large feeding blood-vessels, especially arterial. The hæmorrhage attendant on excision would be dangerous or fatal, and can only be prevented or controlled by ligature.

Accordingly, the objects to be accomplished are; the complete and immediate strangulation of the vascular tissue, observing to include the whole tumour, and well around the limits of the disease; but avoiding the skin, which may either be divided in the intervals of the ligatures, or a single ligature be passed subcutaneously. Small, firm, round whip-cord answers best. The nævus needles are curved, and firmly set in wooden handles, resembling aneurism-needles.

Nævus, of moderate size, and in a situation where cicatricial disfigurement is not of much consequence, may be ligatured by two double ligatures passed underneath the base of the tumour, and crossing in opposite diameters, so as to divide it into four sections; the skin may be either reflected, or divided circumferentially, in the intervals of the

FIG. 21.

ligatures, which are then successively drawn sufficiently tight around the base of tumour, and tied in a reef-knot. An ordinary nævus on a child's head, generally thus admits of ligature. (Fig. 21.) The tumour, when effectually strangled, sloughs in a few days, leaving an open sore, which granulates and cicatrizes.

Nævus of larger size, and so placed that the sacrifice of integument

would entail much disfigurement, may admit of subcutaneous ligature; the skin being left entire in this operative procedure, and consequently not sacrificed by sloughing. The *nævus*-needle, armed with a double ligature, is introduced at some point of the base of the tumour, and carried round its circumference to the same point; the cord is drawn out into a single ligature, the needle withdrawn, and the two ends pulled steadily and tied tight enough to thoroughly strangle the included mass of vascular tissue. If the mass be so large, or so placed, that it cannot be thus encompassed by a single passage of the ligature, then, the needle-point may be made to emerge at a convenient spot, one end of the cord drawn out, the needle withdrawn, and having been re-threaded with that end of the ligature, it is re-introduced at the point of emergence and carried round the remainder of the tumour to the point, where it was first introduced; the operation being completed by strangulation and securing the ligature. A *nævus* on the cheek can be removed by this method, without any resulting disfigurement, more than a puckered appearance. I have known a dragging down of the lower eyelid to ensue, but this can be remedied by the operation for Ectropium. Ligature may be employed at an early period of life; in infants a month or two old, and with a successful result.

ANEURISM BY ANASTOMOSIS, consists of large freely communicating blood-vessels, principally arterial; and the tumour must be removed by ligature, either of the circumferential feeding branches, or of the main trunk of the part.

The former procedure has not been followed by successful results; ten recorded cases having failed, without one single instance of ultimate cure. In two cases, however, where the scalp was the seat of aneurism by anastomosis, Gibson aided the effect of circumferential ligatures by incisions around the tumour in the intervening spaces; and this procedure proved successful.

Ligature of the main trunk has been practised on the carotid, when the tumour was seated on the scalp, or in the orbit; or the brachial, and femoral arteries, have been ligatured, when the disease occurred on the arm or leg. The carotid has been tied in twenty-three recorded cases; in five of which, both arteries were tied at intervals of several weeks. Single ligature proved successful in some of the cases; double ligature in all five. Ligature of the carotid for aneurism by anastomosis in the orbit, has been performed in thirteen cases; with a successful result in the majority.

These two procedures,—ligature of the circumferential arteries, and of the main trunk, may be combined or practised in succession, and the former aided by the intervening incisions.

Excision is also applicable to the larger sized vascular tumours; especially those of a venous character, and those which are encysted. But the situations should be such as to allow of the parts being readily brought together, after the operation. Free excision, moreover, is necessary to prevent the risk of hæmorrhage subsequently, and compression of the coapted parts will be an additional precaution.

OSSEOUS and GLANDULAR TUMOURS, respectively, are more properly considered in connexion with Diseases of the Bones, and Glandular Organs.

INFILTRATING GROWTHS comprise, perhaps, only one genus—*Cancer*: its typical species being Encephaloid, Scirrhus, and, perhaps, Colloid, with

many sub-varieties; distinguished chiefly by shades of difference in their general characters of colour, consistence, shape, size, and mobility.

*Structural Condition, and Diagnostic Characters.*—The three species of cancer present under the microscope the same cell. (Fig. 22.) This, at

FIG. 22.\*

first colourless and pellucid, consists of a delicate envelope, containing a large clear nucleus or two, sometimes more, never less—within each of which is imbedded one or two nucleoli, also large and clear. Such is the “cancer cell.” (Bennett). But is this cell peculiar to, and characteristic of cancer? In considering the diagnosis of cancer, I

shall have occasion to recur to this question.

FIG. 23.†

The cell assumes various shapes; either round, more usually caudate or spindle-shaped; and presents other forms by outgrowths in one or more directions. These cells are deposited in a filamentous stroma or meshwork, which has a variable locular arrangement and closeness of texture. (Fig. 23.) This inter-cellular stroma is probably, in most cases, nothing more than the fibrous tissue of the textures, amid which the cancer-cells are infiltrated. But another inter-cellular substance—gelatinous, translucent, and amber-coloured, may be present in more or less abundance, and this is probably peculiar to cancer,—the colloid species.

The leading species of cancer are further allied by possessing a similar chemical basis: namely, chiefly albumen, associated with fibrine, gelatin, osmazome, fat, certain salts,—such as the phosphates and carbonates of lime, with the carbonates of soda and magnesia, the oxide of iron, and water. But the results of chemical analysis hitherto made are not very reliable.

*Species.*—As the proportion of cells, or of inter-cellular matter, prevails, so do we recognise *Encephaloid*, or cancer, *par excellence*, abounding with cells; and, therefore *soft*, opaque, and of a dead white or fawn colour. Hence the terms *cerebriform* or *medullary*, applied to this form of the disease; and—the cellular or special element of cancer, predominating—encephaloid yields on pressure an abundant quantity of “cancer-juice,” which resembles milk or cream. *Scirrhus*, on the other hand, is far more *fibrous*, and, therefore, *hard* and *craggy*; semi-transparent in a thin section, and of a bluish-white or fawn colour; comparatively little “cancer-juice” is exuded on pressing the cut surface of the fibrous stroma, and this little rather resembles thick gruel than cream, or it may be a small quantity of thin yellow serous fluid exudes; but the fibrous stroma itself contracts, whereby the cut surface speedily assumes a concave aspect, unlike the section of any other tumour, which remains level or becomes slightly convex at its margins.

*Colloid*—in contrast with both the foregoing—is *gelatinous*, owing to

\* Cancer-cells *a*, from scirrhus of the mamma. Transparent cells *b*, seen after the action of acetic acid. 250 diam. (Bennett.)

† Section showing the arrangement of cells and fibrous stroma in scirrhus of the mamma. (Bennett.)

the predominance of the gelatinous, intercellular matter, and in which the cells are suspended; the whole being infiltrated through a delicate fibrous stroma: it appears, therefore, either as a trembling mass, or a glairy fluid—dimly transparent, and of a greenish yellow colour.

Cancer is essentially an *infiltrating* growth; but while this peculiarity almost constantly prevails in scirrhus and colloid cancers, encephaloid becomes *encysted*, about as frequently as it remains free. A very thin, yet distinct fibro-cellular capsule may invest this typical form of cancer, and from which thin partitions pass into the tumour thus defined, intersecting its substance, or investing its several lobes. Generally speaking, this capsule is not adherent to the surrounding textures; it furnishes a *matrix* in which numerous and tortuous blood-vessels ramify, previous to supplying the mass itself with vessels. Encephaloid is, indeed, always abundantly vascular, as compared with scirrhus and colloid, both of which are relatively destitute of blood-vessels. Nerves probably exist in the substance of a cancerous tumour; for pain is felt in scirrhus, and less so in encephaloid cancer, when cut into during a surgical operation. But the question of nerve supply, in point of proportion and distribution, has yet to be demonstrated anatomically, by dissection.

*Tumour.*—The investing capsule, when present, gives a definite outline to an encephaloid tumour—round, oval, spheroidal, or lobed, which contrasts with the irregular and unbounded outline of scirrhus and colloid, the infiltrating course of which is very rarely circumscribed. The boundary of either of these species of cancer is perceived rather by their degrees of consistence as compared with that of the textures around the seat of infiltration.

The greater vascularity of encephaloid, coupled with its *capsular* and therefore more isolated condition, in many cases, are circumstances favourable to a corresponding rapidity of growth, and evolution as a distinct tumour; consequently this, the typical species of cancer, frequently attains an enormous size and protrudes (Fig. 24): but scirrhus being differently circumstanced in these respects remains smaller, rarely acquiring a larger size than an orange, and this rendered indistinct by infiltration of the surrounding textures. It shrinks yet smaller by their condensation and absorption, as its abundant fibrous stroma,

FIG. 24.\*

\* Advanced carcinoma of the mamma,—exhibiting a prominent, fungoid, and bleeding mass. (Cruveilhier.)

continuous with parts around, draws texture after texture within the claws, as it were, of the infiltrating mass. (Fig. 25.) Infiltration

FIG. 25.\*

penetrates onwards, while contraction pulls backward; so that there is a double action at work—like the pulling on of a glove. Colloid cancer, although ill provided with blood-vessels for rapid growth, is scarcely restrained by a contracting fibrous stroma, and—in this particular resembling encephaloid—it spreads to an indefinite size, but not as a distinct tumour.

The circumscribed, or non-circumscribed, condition of cancer, much affects its mobility as a distinct tumour. Encephaloid is often distinctly moveable in the organ or textures in which it is embedded; while scirrhus and colloid can be moved about, only as a diffused mass in connexion with those textures to which the cancer has contracted adhesion by infiltration.

Such are the chief peculiarities respecting the shape, size, and mobility of the three typical species of cancer—in addition to their individual properties of consistence (and colour); and by the concurrence of which characters they can be readily recognised during life.

*Diagnosis.*—No sufficiently exact structural differences have as yet been detected, by which to distinguish these species of cancer-growth; we are, therefore, compelled at present to rely solely on their physical characters to determine the question of their (*differential*) diagnosis, so far as these characters can be recognised through superimposed integuments.

This conclusion refers only to the *comparative* value of structural characters; for many other circumstances associated with cancer—its seat, character of the pain, course, and duration, its influence on surrounding parts, the constitutional symptom of cachexia, and the peculiarities of age, sex, previous diseases of the individual, and hereditary taint—combine to regulate the diagnosis.

But the structural *individuality* of cancer-growth, as a distinct species of growth, is itself uncertain. The supposed characteristic “cancer-cell,” is occasionally absent in tumours, otherwise cancerous; and similar cells may be found, and as often—according to Forster—in healthy as in diseased tissues, and are, therefore, not peculiar to cancer. These two propositions, taken together, *apparently negative* the value of the “cancer-cell,” as the most exact ground of identification.

If, however, structural characters only, are reliable for the exact diagnosis of certain growths—*e.g.*, fibrous tumour, and its recurring fibroid and fibro-nucleated varieties; while in respect to other species of growth—*e.g.*, cancer, the structural individuality of the cancer-cell is equivocal; then, the identification of the latter growth—by virtue of its structural characters—turns upon the question, can the variable conditions of this cell be explained?

In tracing the Law of Structural Retrogression, with regard to the interpretation of the minute structural constitution of growths and other morbid products of nutrition (P. p. 93), it will be seen that the structural element of cancer,—the “cancer-cell,” corresponds to the cartilage-cell,

\* Scirrhus of Breast.—Section showing retraction of nipple.

or to certain epidermic cells,—in various rudimentary stages of their development. Thus may, perhaps, be explained the not unfrequent association of cancer-cells with the healthy tissues whose structural elements are analogous or identical. Excluding, therefore, those *exceptional* forms of growth which simulate cancer in their clinical history, but which do not present the cells of cancer; and excluding also those *exceptionally* healthy tissues with which similar cells are found; this structural element is the most unequivocal sign of the presence of cancer. In like manner, the different species—encephaloid, scirrhus, and colloid—so far as they can be distinguished by structural characters—represent rudimentary stages of analogous cartilage-cells. With reference to the structural individuality of cancer, as a distinct species of growth, and its three leading species or varieties—the value of structural characters is thus fully confirmed, as the earliest and most exact ground of diagnosis.

In not a few cases, I have thus clearly demonstrated the nature of a cancer-tumour; by puncture with a grooved needle and submitting the material withdrawn to microscopic examination.

The three species—encephaloid, scirrhus, and colloid—may possibly coexist and be combined in the same growth. Of this association I once saw a remarkable example in the *post mortem* examination of a patient, who had been under the care of one of my colleagues at the Royal Free Hospital. The abdominal viscera were literally agglomerated into an enormous mass of cancer, which consisted of the three cardinal species above mentioned. A beautiful wax model is preserved in the museum of the hospital. Then, again, these species of cancer may succeed each other, as well as coexist, in the same individual. Yet, with all this fraternization, they never lose their individuality; they never become transformed. On the contrary, each species preserves its own general characters, and this too, through many subordinate varieties. These varieties, like the typical forms themselves, are, in most instances, occasioned by different proportionate quantities of their constituent elements—the cancer-cells and fibrous stroma. Some of them, however, are occasioned by morbid changes of structure; degeneration, and the consequences of inflammation.

*Varieties.*—Many varieties of cancer have been described; of which some are worthy of notice, not because they possess any essential importance, but owing to the characteristic appearances they present. The most important varieties are the following:—They are distinguished and recognised by their physical characters, which have suggested appropriate names. The varieties of *Encephaloid* are,—“mastoid” cancer, so named from its resembling, on section, the boiled udder of the cow. This term was originally proposed by Abernethy. “Solanoïd” cancer resembles, on section, a sliced raw potato. It is hard, almost homogeneous, pale yellow, and crisp; hence this name, which was first suggested by Recamier. The substance of such a mass yields milk-like fluid in abundance, under pressure, and eventually softens. The “milt-like” tumour, so named from its general resemblance to the milt of certain fishes. (Monro Tertius.) “Nephroid” cancer exhibits, on section, a peculiar arrangement of the fibrous stroma, and a semi-transparent watery glossiness, with other characters, not unlike those which the section of a kidney presents; whence its name. (Recamier.) “Fasciculate” cancer is another variety suggested by the peculiar appearance of its fibrous structure. (Müller.) The coexistence of softness, and linear or fibrillar arrangement, constitutes its most readily ascertainable peculiarity.

(Walshe). "Hæmatoid" cancer is a variety of encephaloid, in which the brain-like character is associated with an unusual amount of vascularity, the vessels sometimes interlacing so as to constitute a dense and somewhat spongy network, without, however, the peculiar structure of erectile tissue. "Fungus hæmatodes" is rather an advanced stage of encephaloid, than a variety of this species of cancer. It represents the occurrence of interstitial hæmorrhage, which either infiltrates the whole mass, or forms irregular accumulations of blood in its substance; and ulceration of the integuments taking place, a fungoid bleeding growth protrudes. "Villous" cancer is a term somewhat expressing the appearance presented by this variety of encephaloid. It is very vascular, and apt to bleed copiously. This and its other characters are well marked when the disease occurs on the mucous membrane of the urinary bladder. It is described by Rokitsky as "dendritic vegetation;" an excrescence consisting, in its stem, of a fibroid membranous structure, on which the branches and villous flocculi are borne, as larger and smaller pouch-like and flask-shaped buddings, or sproutings of a structureless hollow tissue. "Melanotic," or melanoid cancer, is, with very rare exceptions, medullary cancer modified by the presence of black pigment in its elemental structures. (Paget.) This is a species of degeneration, besides which, encephaloid is subject to fatty and calcareous degenerations. Other morbid changes are suppuration and sloughing, which it is very liable to undergo.

The varieties of *Scirrhus* are:—So-called "Chondroid" cancer, which is an early stage of scirrhus, dense and crisp; exhibiting, on section, an unusually shining aspect, and bluish-white colour. (Recamier.) "Lardaceous" cancer is occasioned by the infiltration of scirrhus through the substance of an organ, which then frequently appears not unlike the boiled rind of bacon. "Napiform" cancer is so named from the peculiar arrangement of its fibrous stroma, which, on section, has some similarity to a cut turnip. (Recamier.) "Apinoid" cancer derives its name from the striking resemblance presented, on section, to the cut surface of an unripe pear. This similitude arises from the dissemination of comparatively opaque and almost buff-coloured spots through a translucent ground of very pale yellowish-lilac tint. The quantity of more opaque substance gradually increases, and eventually predominates, so as to alter the appearance of the surface completely. (Walshe.) Allied, is the "reticular" cancer of Müller. "Hæmatoid" scirrhus is a condition of rare occurrence; but when it does happen, its peculiarities are of the same kind as those of the hæmatoid variety of encephaloid; differing, only in being less fully developed. (Walshe.) "Osteoid" cancer, or ossifying fungus growth (Müller), occurs as a tumour, consisting chiefly of bone, but having on its surface, and in the interstices of its osseous parts, an unossified fibrous constituent, as firm as fibrous cartilage; after a time, similar growths ensue in parts distant from the seat of the first-formed, and not on bones alone, but also in the cellular tissue, serous membranes, the lungs, lymphatics, etc. It would appear to be the calcareous or osseous degeneration of scirrhus, or of medullary cancer, with which it not unfrequently coexists. Uninterrupted gradations may be traced between the osteoid variety and these typical forms of cancer. (Paget.) Scirrhus is subject to other species of degeneration, and to morbid changes in common with encephaloid. Ulceration is more frequently observed in the course of scirrhus.

*Colloid* cancer is singularly exceptional in not presenting varieties, properly so called. Nevertheless, the quantity of fibrous stroma, or of colloid matter, may respectively predominate. If the former, then this species assumes the appearance of a very tough, white, fascia-like mass, in which are small separate cysts or cavities, filled with the colloid substance. In the opposite extreme, large masses of colloid matter appear to be only intersected by fibrous white cords or thin membranes, arranged as in areolar tissue, or in a wide meshed network. (Paget.) Another variety refers to the *quality* of the colloid matter, rather than its quantity. It may be, or become, white and pearly, or opaque. I once met with a remarkable specimen of colloid cancer, in a female patient at the Royal Free Hospital (1862), and which I carefully examined. Most of the abdominal and pelvic viscera were affected with this disease;—namely, the stomach; the intestinal canal, which was beset externally, here and there, with pedunculated masses of colloid, somewhat resembling plums on their stalks; two colloid masses were imbedded in the spleen; the pancreas was wholly converted into the same gelatinous substance, enclosed in loculi; the bladder was distended with a trembling mass, which rolled out like a jelly, leaving the mucous membrane pulpy, ragged, and bloody. The substance of the uterus and ovaries was infiltrated with drops of colloid, together forming a mass which seemed to be incorporated with a similar condition of the rectum. The gelatinous matter thus extensively diffused, was in some parts white, and of brilliant pearly transparency, looking like colourless and clarified jelly throughout the pancreas; white and opaque in the spleen and uterus; while it presented its usual amber colour and transparency in the other organs I have specified. This *opacity* of the colloid matter was probably due to molecular disintegration.

Such are the principal varieties of each of the three typical species of cancer. Some of them are, as I have said, the result of certain *morbid* changes, to which cancer itself is liable; they are illustrations of a pathological law which prevails extensively—that morbid products themselves undergo morbid changes—the diseases of diseases. Hence their almost numberless, and sometimes perplexing, complications.

**CYST-FORMATION.**—A further illustration of this law, I have yet to notice in relation to cancer. This relation, if not one of accidental association, represents an actual substitution of cyst-formation for cancer-growth, and at the expense of its own structural elements. Thus cysts may either be formed with cancer; or from and out of the cancer-structure, by their erring development and growth.

Mr. Paget's work contains the best summary of this subject, of which the following is an abstract.

(1) Respecting cysts accidentally associated with cancer, but of *independent* formation.

Scirrhus of the mammary gland may occupy a portion of it only, in the rest of which many cysts may be formed, that are in no sense cancerous; or, the chief lactiferous tubes may be dilated into pouches or cysts, contiguous to, but quite independent of, the neighbouring cancer-growth. Such a cancer may nevertheless in its course enclose these cysts, and they remain for a time imbedded in its substance. The ovary may be the seat of cysts, and also the seat of cancer; the two growths thus accidentally associated, will probably become connected, although of independent origin. Further than this, cancers may grow from the *walls*

of common cysts—*i.e.*, of cysts which have not originated in cancer-structures. Medullary cancer, especially the villous form, sometimes grows from the walls of cysts which have themselves no cancerous appearance.

(2) Cysts *derived from cancer structures*—by their erring development and growth—constitute a series parallel with that of the cysts barren and proliferous, which form in innocent tumours, or in the natural textures. Cancer-cysts having this origin, are, therefore, either barren or proliferous.

Of the *barren* species are:—Cysts filled with serous fluid, variously tinted. Serous cysts are often born in cancers, especially in those of the medullary type, which grow quickly, or to a great size. One or many such cysts may be present on the surface or in the substance of a cancer. Sometimes a single cyst of this kind enlarges so as to surpass the bulk of the cancer, exceedingly perplexing the diagnosis. Sometimes many cysts are present, as if the tumour were entirely composed of them, with cancerous structure only in their interstices. Sanguineous cysts are born as often as serous, in medullary and other cancers. The imprisoned blood undergoes changes in respect of colour and consistence, thereby diversifying considerably the appearances presented by cancers containing these cysts. Colloid cysts, *i.e.*, cysts containing a glairy jelly—not cancerous—may likewise be developed in cancer-growths, by conversion of their structural elements.

The *proliferous* cysts which originate in cancers, bear on their inner surface cancerous growths—thus corresponding with the glandular growths which spring from the interior of cysts in the mammary and thyroid glands. These endogenous growths are often found in the alveoli of colloid cancer. Clusters of clavate, or flask-shaped villous processes, resembling those formed in the early stages of “dendritic vegetation” of villous cancer, spring from the wall of the alveolus.

The *origin and modes of development* of these cysts—simple and proliferous—have been traced by Rokitsky, and shown to correspond with those of all other cysts: the only difference being the *source* of the cyst-formation—here a cancerous element, while in respect of all other cysts it is an element of some natural tissue.

*Situation.*—The preference of Cancer for different tissues and organs, ranges according to the following average scale. (Rokitsky.)

“First; the uterus, the female breast, the stomach, the large intestine and especially the rectum; next, the lymphatic glands, especially as retro-peritoneal cancer-accumulation in front of the vertebral column; hepatic, peritoneal, cancer; bone-cancer; cancer of the skin, and of the lips; of the brain; of the globe of the eye; of the testes; of the ovary; of the kidneys; of the tongue, and the œsophagus; of the salivary glands and parotid;”\* to which I may add—without pretending to determine their relative places in the scale of frequency,—cancer of the urinary-bladder, of the pancreas, and of the spleen; in each of which organs I have seen, as already described, masses of colloid. In the remarkable case referred to, other organs were similarly affected; the stomach, intestinal canal, uterus, ovaries, and rectum.

This scale does not specify the particular *species* of cancer, in each of the different tissues and organs named; yet their relative liabilities in this

\* Pathological Anatomy. Translated. Syd. Soc., 1854, vol. i.

respect is a matter of great practical importance, considering the unequal degrees of "malignancy" evinced by the several species of this growth.

(1) *Encephaloid-cancer*—the most malignant species; selects first, in order of frequency, the *testicle*; next, the bones and particularly the femur (Paget); the intermuscular cellular texture of the limbs; the eyeball or orbit; the breast; the walls of the chest, or abdomen; the lymphatics. Moreover, encephaloid "occurs in organs in which no other cancer, least of all scirrhus, ever occurs,—as in the liver, the kidneys, the lungs, the testicle, the lymphatic glands." (Rokitansky.)

Encephaloid cancer is not usually *solitary*. It commonly co-exists in many textures and organs.

*Melanotic cancer*—mostly a variety of encephaloid, by pigmentary degeneration of its cells, and the most common of all melanotic tumours—is prone to grow first, in or beneath pigmentary moles (Paget); or selects first the liver (Rokitansky); but it may occur "in the brain and about the nerves; at the eyeball, in the lungs, thyroid gland, liver, spleen, kidneys, bones, lymphatic glands, ovaries, in and beneath the intestinal mucous membrane, between the mesenteric layers, in the skin and subcutaneous areolar texture, upon serous membranes, in the dura mater, upon and within the heart."

This variety of cancer occurs as secondary formations, in very many textures and organs, simultaneously.

*Villous cancer*—another variety of encephaloid—is produced, according to Rokitansky, exclusively upon membranes; more especially upon mucous membranes, and most of all that of the male *urinary bladder*, near the opening of either ureter; next to this the mucous membrane of the stomach, and in particular the pyloric portion. It has been observed suspended by a pedicle from the internal membrane of the rectum, and even from that of the gall bladder. Secondly, it is very apt to grow extensively from the internal wall of ovarian cysts—*cysto-carcinoma*—where it is recognised as villous cancer by its copious accompaniment of medullary sap. In these cases, it is often concurrent with cancerous infiltration of the lymphatic glands about the lumbar vertebræ, and with peritoneal cancer—representing villous cancer upon a serous membrane. It has been observed also upon the dura mater; occasionally upon the general integument; and perhaps in bone. Lastly, it occurs in *parenchymatous organs*.

(2) *Scirrhus* cancer selects first the *breast* in the proportion of 95 per cent. (Paget.) Next, in order of frequency, the stomach; perhaps still more frequently, in this organ (Rokitansky); then, according to the last-named authority, the colon in its sub-mucous cellular tissue; more rarely in the vaginal portion of the uterus; upon serous membranes, and in the subserous areolar tissue. Again, as an expansive degeneration of the omentum, and of the mesentery; in the salivary glands; in the fibrous tissue of the bronchi. In several of these, as well as in other structures,—for example, the ovaries and the brain,—there occur "cancerous growths of embryonic composition, and in all likelihood of fibro-cancerous (scirrhus) nature." To this list may be added cancer-growths *secondary* to scirrhus, and which, in proportion as they are consecutive, incline more and more to the condition of encephaloid; for example, of the lymphatic glands, the bones, muscles, skin.

Scirrhus cancer is not unusually *solitary*.

(3) *Colloid-cancer* selects the *stomach* and *large intestine*; the serous

membranes, and particularly the peritoneum. In other textures and organs this species is mostly *secondary*; as in the lymphatic glands, the lungs, the ovaries, the bones, the breasts; "and in rare cases, the kidney, uterus, and liver." (Rokitansky): to which I may add, the pancreas, spleen, and urinary bladder.

Colloid cancer is usually *solitary*.

ORIGIN.—*Age* has no definite influence on the production of Cancer; the three species having been known to originate at every period of life. Even during intra-uterine life, scirrhus in the heart was found in one case. At birth, meningeal cancer, and instances of cancer affecting other organs, have been found. In infancy, childhood, maturity, middle age, the decline of life, and extreme old age—even at ninety-three—cancer is liable to occur. But certain periods of life are prone to cancer growth, as indicated by its mortality; the tenth to the fifteenth year is least liable, the thirty-fifth to the eightieth year, and perhaps to a later period, is most liable, the tendency increasing with each succeeding decennial period. There seems to be a more rapidly increasing tendency after thirty and onwards for some years, as compared with the same number of years before that period; the proportion of deaths, in both sexes, from the age of thirty to forty increasing to six times more than between twenty and thirty.

*Sex* much affects the liability to cancer. Thus, from forty to fifty years, in females, the mortality increases sixfold; whereas, in males, the number of deaths increases only two and a half times.

*Sex* in relation to *Species*.—Scirrhus is more common in the female; epithelial cancer, in the male.

*Age* in relation to *Species*.—Encephaloid occurs most frequently in infancy and youth; scirrhus, in adults, it being uncommon before puberty or even the thirtieth year; colloid in adults only, or excessively rarely, if ever, before the thirtieth year.

*Hereditary* tendency.—Evidence in this direction may be resolved into two general facts. In some families cancer is known to have occurred in more than one individual. Mr. Sibley traced it among cancer patients at the Middlesex Hospital, in one case of every nine; by Mr. Paget, in one of every six cases. Mr. Arnott and Mr. De Morgan each had charge of members of a family in whom disease was thus exhibited; the father and his relatives were healthy, the mother died of cancer of the breast, two of her sisters of phthisis, and one of dropsy. Of six daughters, five had cancer of the breast, the youngest was still healthy, and the only son died of phthisis. On the other hand, to give some force to such observations; some *entire* families are exempt from the disease.

*Constitutional* tendency to cancer can only be inferred—yet the inference is strong—from the apparently negative relation of this disease to any *external* causes. The various presumed external causes of chronic maladies shall continue in operation in many individuals, for a length of time with every degree of intensity and in all possible modes of combination, *without* producing the slightest manifestation of cancer; and cancer exercises its most fearful ravages in persons who have never been influenced by any such causes. Excluding, therefore, external causes, some internal and individual, or constitutional tendency must have been in operation.

On the other hand, there are reasons for believing that cancer, like syphilis, is primarily *local*, and only secondarily, constitutional. Velpeau is, perhaps, the leading authority who supports this position;

and the reasons adduced are thus stated by Mr. Erichsen in his work on Surgery :—

(1) Cancerous tumours spring up in individuals who have always enjoyed perfect health, and who, to all appearances, are perfectly well at the time of the occurrence of the disease.

(2) These tumours are not unfrequently the result of some local injury or irritation.

(3) The constitutional health does not, in the majority of cases, appear to suffer until some months have elapsed; when, as the lymphatics or glands become implicated, or neighbouring tissues invaded, signs of cachexy set in.

(4) If the disease be removed before neighbouring parts have become contaminated, the health, if it have suffered, often improves materially.

(5) The patient remains free from any recurrence of the disease for a considerable period; in the great majority of cases.

(6) In some instances, no recurrence whatever takes place, the disease being eradicated from the system, which could not be the case if it were constitutional.

(7) Recurrence having taken place soon after an operation, it is almost invariably either in the cicatrix or in its immediate neighbourhood; owing to cancer-cells which had been widely infiltrated escaping removal; and subsequently developing into a new tumour. Were the disease constitutional, recurrence would be as likely to take place in other parts, or in internal organs, as it does when the operation has been too long delayed.

(8) The same tendency to recurrence after removal, and even to secondary deposit in distant organs, is observed in respect to other tumours which are incontestably, primarily local—*e.g.*, the fibro-plastic and the enchondromatous, and which only become constitutional in their more advanced stages, and in a secondary manner.

This last proposition seems to me fallacious; both the tumours adduced being “localized” growths, although the fibro-plastic or myeloid variety of enchondroma is undoubtedly a recurring tumour.

*External causes.*—*Injury* or irritation, is not found to have more than a limited influence on the production of cancer. A broken tooth scratching the tongue or cheek, may induce the disease in either of these parts; the friction of a clay-pipe, constantly used, may excite cancer of the lip; and the irritation of soot in contact with the scrotum or prepuce appears to induce the well known chimney-sweeper's cancer of those portions of integuments. In all such cases, the cancer produced is the epithelial variety.

*EFFECTS of Cancer, as an internal cause.*—(a) *Locally.*—*Pain* may be regarded as an effect, produced, apparently, by compression of the nerves in, and around, the cancer-growth; by separation of their fasciculi and fibrils with interstitial deposit; and, in the case of scirrhus by dragging of the nerves as the growth contracts. Pain is, therefore, due rather to a *mechanical* operation of the tumour, than arising from any vital endowment of the growth itself, which is in fact comparatively destitute of nerves. *Encephaloid* cancer, especially, is of this character; the tumour scarcely seeming to be sensitive, when cut into during a surgical operation for its removal.\* *Scirrhus*, however, seems more especially to

\* System of Surgery. Edited by T. Holmes. Cancer, by C. H. Moore, vol. i. p. 526.

give rise to pain from *within* itself, the pain radiating thence along the nerves.

The kind and degree of pain vary considerably. Lancinating pangs, particularly when the tumour is handled, are commonly experienced in scirrhus. A hot dart, molten lead, and other such expressions are also used to denote both the character and severity of the pain in this species of cancer. The pain of encephaloid is generally less severe; and colloid is comparatively painless. In cases taken indiscriminately the pain differs; a dull aching sensation, a feeling of weight and coldness, distressing itching, represent these varieties.

The pain varies also in point of date, duration, and constancy. Thus, it is not generally of early occurrence; being absent in most cases of scirrhus breast, for the first year or year and a half. Its duration is temporary; occurring occasionally, as when the breast is handled. And cancer, not uncommonly, runs through its whole career without any pain. It is absent in about one-fifth of the cases, including all organs and localities. (Walshe.) The pain is usually proportionate to the rapidity of growth; becoming more severe and persistent when the tumour is inflamed or ulcerating or about to slough, and acquiring the hot burning or scalding character.

*Derangements of function* are produced, some of which are *irritative*; as pleurisy and hydrothorax by mammary cancer, peritonitis by ovarian cancer, vaginal discharge by non-ulcerated scirrhus of the uterus. Other derangements are *mechanical*; as effusions by the compression and obstructions of blood-vessels, spontaneous fracture with cancer of bone, stricture of the urethra or bowel, pressure on the brain, spinal cord, or nerves, inducing paralysis, partial or complete, pressure on the optic nerve or from within the eyeball, impairing or destroying vision.

(b) *Constitutional effects*.—The functions of the various parts of the body, other than of the part affected, may continue uninterruptedly for a longer or shorter period as cancer advances. Thus then the general health remains unimpaired, independently of the local disease. Conversely, the *growth* of cancer is inversely proportionate to the general health; being temporarily arrested, if it remain unaffected or is maintained, and coming into activity as it declines. Consequently, with advancing age, there is, so far, a greater liability to cancer; and particularly of the uterus, during the decline of generative power. In like manner the functional vigour of any part of the body apparently protects that part against the production and growth of cancer; whereas the decline of such vigour has the opposite tendency. Thus, pregnancy and lactation protect the uterus and breasts, respectively; while the cessation of those functions is favourable to cancer-growth in these organs. The supervention of either of the functions referred to, is, however, sometimes accompanied with a rapid extension of the disease, or the tumour may remain unaffected by these local changes.

*Cachexia* is the term used to denote all those functional derangements, chiefly of the circulation, nutrition, and innervation, which together represent the constitutional condition. Feverishness, loss of appetite, nausea and vomiting, distressing thirst, imperfect digestion, obstinate constipation or diarrhoea, *progressive emaciation* with *peculiar yellow sallowness*, muscular weakness, sleeplessness, and melancholy; such are the leading phenomena of this condition. They are somewhat proportionate to the amount and diffusion of cancer-growth in the system; and hence

are more pronounced when it appears in different parts successively, as secondary cancer, and as affecting especially the great internal organs, which minister to the nutrition of the body. Cancerous cachexia is most marked in scirrhus, and least in colloid cancer; encephaloid taking an intermediate position, but being more nearly allied to colloid, in this its constitutional influence.

*Co-existing Diseases.*—Diseases of various kinds may co-exist with cancer, without apparently influencing it, or being influenced by it. Thus, Bright's disease of the kidney has no effect on the course of cancer, which may proceed favourably, even to withering and complete cicatrization, independently. Extensive skin disease, syphilis, caries of the spine, fatty and cirrhotic liver, may severally co-exist. "But, observes Mr. Moore, exanthematous fevers are unknown in the cancer wards of the Middlesex Hospital, excepting erysipelas, which is not less common in such patients than in others. Erysipelas sweeping over a cancerous ulcer will sometimes efface its specific characters, rendering it a healthy, granulating, and cicatrizing sore. In a few days, or weeks at most, the original kind of ulcer has reappeared. Hospital gangrene, occasionally, has a similar temporary effect, and ultimately the same result. Apoplexy and heart-disease seem to have some protective influence against the production of cancer. Tubercle appears to be no less manifestly incompatible with cancer, while yet related to it." Traces of old tuberculous disease are remarkably common in the bodies of persons dying with cancer, and in 34 per cent. of them phthisis exists in the family; yet the two diseases are never found in active growth together in the same person. Active tubercle co-existing, supplants as it were, cancer, which may wither and even cicatrize as the patient is rapidly dying of phthisis.

*COURSE.*—In the vital history of cancer, certain aspects of its progress, subsequent to the more immediate effects already stated, are particularly worthy of observation.

*Rate of Growth.*—Encephaloid cancer takes the lead, growing generally to some dimensions in a short time, or even with vast rapidity. Scirrhus grows more slowly. Colloid with a medium degree of rapidity.

*Duration of Growth.*—Scirrhus is of longest mean duration, averaging three or four years; encephaloid is of shorter mean duration, averaging about two years; colloid holds a middle place also in this respect.

Sex appears to have but little influence on either the rate or duration of growth.

Age seems to have some influence; the progress of cancer, generally, being more rapid in the young, and chronic in old persons.

*Arrest and Decay.*—These changes consist in a cessation of growing, and a destruction of the proper structural elements of the tumour. Cells and nuclei break up, oil-globules and granules are substituted. The chief element in a *withering* cancer is fat, thus contrasting with the general emaciation of the body.

*Softening*—which contrasts with the hard withering of cancer—takes place, principally, in encephaloid, its soft cancer. It then consists of matter having a creamy or milky appearance, very slightly viscid, and the consistence of soft cheese or thin pus. The proportion of milky opaque fluid, yielded on gentle pressure, indicates the progress towards this change. As affecting colloid cancer, softening represents, not perhaps any further change in its already jelly-like matter, but the breaking down

of its containing stroma, with rupture of the loculi and escape of their contents.

The commencement of softening, in any species of cancer, is either at the circumference or centre of the tumour; and in a single spot, or in several spots, simultaneously.

Age seems to have no definite relation to these changes. In old persons, the arrest of cancer is not an uncommon event. One such case, under the care of Mr. Cooke in the Cancer Hospital, was that of a healthy-looking woman, with a ruddy complexion, and aged eighty-two. Scirrhus of four years' duration existed in her left breast, and she had been an out-patient just twelve months. Another instance, in the University College Hospital, was that of a woman aged seventy-seven. The disease had existed for seven or eight years, but was progressive during the last eight or nine months.

**TERMINATIONS.**—(a) *Resolution and Absorption* is one mode of *spontaneous cure*. Thus, an encephaloid cancer of the eye of an infant ultimately disappeared, and was followed by dropsy and atrophy of the eyeball. Scirrhus of the breast disappeared in a lady whose other breast had been extirpated for this disease. But, in this case, scirrhus was found in several of the abdominal viscera; the patient having died of asthma not long after the subsidence of the breast-cancer. (b) *Suppuration* is another mode of spontaneous cure. A man had a large scirrhus tumour removed from his back. The disease returned. No operation was again performed; but subsequently violent inflammation supervened, an abscess followed with profuse suppurative discharge, and then recovery. (c) *Mortification* may extirpate a cancer, though rarely. The whole tumour is eliminated by sloughing in a mass. [P. p. 808.]

**Cancerous Ulceration and Ulcer.**—The former consists in the molecular disintegration or destruction of the structural elements of the textures, as in ordinary ulceration, preceded, however, by interstitial infiltration circumferentially; thus differing from ordinary ulceration. And the infiltrating cancer-elements, although themselves dying, seem to exercise a destructive influence over the proper textural elements.

The *ulcer* resulting from this process, presents certain appearances which are most characteristic in the scirrhus ulcer. Of variable size and shape; the edges, at first perhaps thin, irregular, and level with the surrounding surface, or sunken, undermined, and inverted, become thickened, elevated, and everted—a condition commonly observed. The bordering skin acquires a bluish red, or brown tint; and the surface, excavated and irregular, presents large prominent granulations, or a base of slough and blood. A thin, greenish, fetid, and acrid discharge—*ichor*, oozes from the ulcer. Other changes may occur which more or less obscure these appearances, but they are chiefly exceptional or accidental. *Hæmorrhage*, for example, may be profuse, and particularly from the ulcer of encephaloid cancer. The capillary vessels are the usual source of this hæmorrhage; but it sometimes proceeds from erosion of the larger vessels, or from rupture of the varicose veins communicating with the ulcer. An admixture of melanotic matter may occur, as seen also in the ulcer of encephaloid cancer. Then again, a cancerous ulcer is subject to those pathological processes which affect an ordinary ulcer; as inflammation and phagedæna.

A cancerous ulcer enlarges slowly or rapidly, both circumferentially and in depth, the whole area of the textures being infiltrated with cancer-

elements. Consolidation increasing, the ulcer becomes firm and fixed, both in its margins and base; scirrhus ulcer especially acquires these characters, like this species of cancer in the course of its growth. Hardness and immobility, superadded to the appearances of margin and surface already described, renders the cancerous ulcer more characteristic.

*Cicatrization and Cicatrix.*—Paradoxical as it would seem that any process of healing should take place in a cancerous ulcer—itself inherently destructive and texturally indisposed to heal—nevertheless, cicatrization supervenes occasionally. Unlike that of an ordinary ulcer, this cicatrization rises over the prominent granulations and dips into the hollows of the ulcer. In the majority of cases, the process and its result are only temporary; as when erysipelas sweeping over a cancerous ulcer renders it a healthy cicatrizing sore, for a time. But, in some cases, the healing is established, and a sound cicatrix permanently formed. This has occurred in the ulcers of both scirrhus and encephaloid cancers. Of such unusual permanency, a case is related by Nicod, and several others were observed by Bayle. [P. p. 808.]

The *Cicatrix* of a cancerous ulcer is, in some respects, peculiar. It is extremely thin, of a red or violet colour, and often traversed by large vessels. Contraction is restrained by the firmly adherent skin around, the cicatrix is thus rendered very tense and even more attenuated, and disposed to ulcerate again.

*Recurrence of Cancer, locally.*—This is a very common event in the vital history of cancer, whether after its separation spontaneously, or removal artificially by the knife. Local reproduction takes place under different circumstances, which are classed, by Dr. Walshe, as follows.—(a) The process of cicatrization may not distinctly commence, or be interrupted at an early stage, and fungating growths spring from some part of the ulcer or wound. (b) A perfect cicatrix forms, and after a variable lapse of time, a tumour grows in the subjacent tissues, presses outwards the newly-formed scar, destroys it, and appears externally with the characters of cancer. (c) In the cicatrix itself, reproduction may occur, by the development of tuberiform cancerous growths. (Fig. 26.) Encephaloid is the species of cancer usually presented, whatever was the original growth. Colloid perhaps never forms consecutively to either of the other species of cancer-growth.

Recurrent cancer is said to grow more rapidly than the primary cancer.

*Dissemination of Cancer in the System, —Secondary Cancer.*—(a) In textures *continuous* with that, or those, of the original growth. Continuity of tissue is here the medium of communication, directly permitting of infiltration. The textures which thus convey the cancer-elements, may be naturally continuous, or connected by adhesions. Of the former,

FIG. 26.\*

\* Returning scirrhus in the breast, after operation; presenting a series of nodules in and around the cicatrix. One in the centre has ulcerated. (Cruveilhier.)

Mr. Moore saw an instance where the only cancer in a lung was a small portion of an out-growing cancerous gland of the posterior mediastinum, and the only infected absorbent in the root of that lung was one of considerable size, not more than an inch from the implanted cancer. (*b*) In *contiguous* textures also cancer may, apparently, spread, without any direct medium of infiltration. Thus Dr. Hodgkin and other pathologists mention cases, in which an ovary, the mesentery, or the liver, being the seats of cancer—the parts in contact with those organs, as the intestine, the walls of the abdomen, the supra-renal capsule or kidney itself—became similarly diseased. (*c*) In textures and organs *remote* from the original growth, secondary cancer may appear.—(*a*) The *lymphatic* vessels are undoubtedly one channel of transmission. The almost unexceptional infection of the lymphatic glands in the neighbourhood of a cancerous growth,—and which is, indeed, one of the generically distinctive characters of cancers, as a growth—supports this view. Such infection, in relation to primary cancer, is parallel to bubo, in relation to chancre. Either, however, may also be regarded as part only of the primary disease. But cancer can be traced further in the lymphatic system, progressively infecting glands more and more remote from, yet still directly connected with, the part in which the growth first appeared. Surely this diffusion of cancer is secondary. In only about one out of every forty-three cases of fatal cancer is there secondary deposit in internal organs, without infection of the intervening lymphatic glands, *en route*, connected with the site of the external primary disease. (*β*) The *veins*, and venous circulation, would appear to be far less a medium of transmission. Cancer-elements having entered the venous system, through the thoracic duct, the lung as the proximate organ, would next become the seat of cancer-deposit. Yet, in 173 cases of cancer, the lymphatic glands were infected in 140, the lungs in 22 only. The fact, however, of both these organs being affected, in most cases, and simultaneously, indicates the agency of the pulmonary venous system. (*γ*) The *arteries* and arterial circulation are engaged even less definitely than the venous circulation. Arterial blood flowing to all parts alike, they are not equally prone to cancer. The liver is first in order, thus contrasting with the lungs, among internal organs. It was the seat of secondary cancer in 60 of 173 instances taken indiscriminately, and in 60 of only 90 cases in which the disease spread at all beyond the lymphatic glands of the part first affected. The kidney is far less liable,—it was attacked with consecutive cancer twice only in 173 cases; and the spleen but once in that number. The bones and serous membranes, are both commonly invaded. These differences of liability suffice to show the extreme irregularity of secondary cancer, in its presumed relation to the arterial circulation, as the medium of transmitting cancer-elements from the primary growth.

One general law respecting the dissemination of cancer in the system, would seem to be this;—it is regulated, in some measure, by the retention of cancerous matter within the body, or its discharge externally through the integuments by ulceration or through some natural passage. Cancer of the uterus with free discharge per vaginam, is followed by secondary cancer in not more than 25 per cent.; whereas deep-seated cancer of the breast produces secondary cancer in 79 per cent. In calling attention to this important general fact, Mr. Moore justly adds, there are covered cancers, though very few, which remain solitary to the

end of life, and there are cancers on free surfaces which do become disseminated.

The successive dissemination of cancer in the system, or primary and secondary cancer, must not be confounded with the *simultaneous* dissemination of cancer, or the production of more growths than one, in different parts, at the same time. The total absence, probably, of functional symptoms, at an early period is apt to mislead—*e.g.*, in cancer of the brain, lungs, liver, and stomach, organs of leading functional importance. Thus cancers which are apparently successive may really be simultaneous.

The *relative tendency* of the three species of cancer to affect the system secondarily, differs with respect to each. Encephaloid and scirrhus seem to dispute the first place in this aspect of their vital history. But colloid undoubtedly has here the lowest rank, as also in the other characters of malignancy.

*Species and shape* of secondary cancer—Encephaloid is produced in the majority of cases; Scirrhus far less frequently, and even rarely. Colloid has not yet been found, in any case recorded. (Walshe.)

The nodular form is that which secondary cancer usually assumes, especially in the liver, lungs, and bones. In a cicatrix, as after excision of a cancerous breast, this form of secondary cancer is very common. Nodules or button-like tubercles appear which spread and coalesce; or a hard ridge forms in the line of cicatrix. In either case the colour, whitish at first, deepens into a purplish-red hue.

In proximate lymphatic glands, secondary cancer produces—and probably at an early period—tenderness, enlargement, and induration, increasing even to bulletty hardness.

*Termination by Death.*—This, the natural and most frequent issue of cancer, takes place in various ways, which may be concurrent or successive. (a) By the *constitutional* influence of the disease on nutrition and blood-production, as manifested by cachexia; the proper cancerous death. (b) The direct influence of the disease, *locally*, on various functions—*e.g.*, of the liver, stomach, œsophagus, intestines. (c) Hæmorrhage, internally or externally—*e.g.*, Cancer of the uterus. (d) Exhaustion from pain and discharge—*e.g.* Cancer of the uterus. (e) Mortification—*e.g.*, cancer of the limbs. (f) Intercurrent diseases, generally of the inflammatory class—*e.g.*, pleurisy, or pneumonia, by cancer affecting the ribs and lung. (g) Substitute diseases—*e.g.*, Phthisis supplanting cancer; tubercular deposit (in the lungs) being pathologically equivalent to the cessation of cancer-growth in some other part of the body.

*TREATMENT.*—Naturally incurable and fatal as cancer is, generally, it may undergo certain structural changes of a self-curative character, the purpose of which it should be the aim of therapeutics—medical and operative—to imitate. To establish this correspondence between the treatment of injuries and diseases and the processes of Pathology, in respect to their natural courses and tendencies, is one of the leading features of modern Surgery; and this relation of art to the indications of nature, is better illustrated by the treatment of Cancer than by that of any other Morbid Growth.

1. *Arrest of Cancer, and Hygienic and Medicinal Treatment.*—The natural arrest and decay of cancer consists in the cessation of growth, and the disintegrative destruction, of its proper structural elements; changes which are accompanied with, and denoted by, *withering* of the Tumour.

This course and termination are observed mostly in the career of scirrhus, as witnessed best in the puckered-up chronic mammary cancer and shrivelled breast of old women. No known medical treatment seems to insure this result; although iron, bark, cod-liver oil, the anodyne influence of opium, and such other medicinal agents as, apparently, improve nutrition; are auxiliary. But hygienic measures, especially in the shape of a generally nutritious and easily assimilated diet, and a cheerful, hopeful tone of mind, are most efficacious. The growth of a cancer-tumour is inversely proportionate to the arrestive influence of the general health. Thus, when the body is well nourished, the tumour starves.

*Local* applications are advantageous resources occasionally. Any temporary supervention of inflammation may be treated accordingly, by a few leeches or a light poultice. Pain recurring or persistent, and affecting the general health, is often mitigated by a belladonna plaster, or by conium or opium ointment. A scruple of the iodide of lead in a drachm of glycerine, mixed with an ounce of unguentum opii, is recommended by Mr. Moore. Gently rubbed over the tumour two or three times a day, it reduces any swelling, as well as relieves pain. Soap plaster, used simply to protect, not to compress, the integument, is also calculated to retard the progress of the growth.

Compression may control pain, but its efficacy in repressing growth is doubtful. First tried at the Middlesex Hospital many years since, it was unfavourably reported on by Sir Charles Bell; subsequently, highly extolled by Recamier—who stated that 30 per cent. of his cases were cured, and advocated by Dr. Walshe—it has, nevertheless, not found much favour in this country. Compression is best effected by means of the air-cushion and spring, devised by Dr. Neil Arnott. Pressure varying in force from two-and-a-half to twelve or sixteen pounds can thus be brought to bear on the tumour.

2. *Sloughing and Enucleation*; (a) *by cauterization*.—This method of treatment is warrantable only in cancer which is already *ulcerated*, and has acquired adhesions beyond the fair reach of the knife.

Cancerous glands, as an extension of the disease, are not so conveniently removed by the application of caustic. But they, and the textures around the slough, mostly become notably diminished in size; an important fact with reference to the glands, compared with their progressive enlargement after removal of the primary tumour by excision. Velpeau's observations seem to confirm this difference in favour of treatment by caustic. It may be followed by successful results, but of temporary duration; a few weeks only—if the disease be incompletely extirpated, or lasting until after the wound has healed—if a healthy granulating surface was obtained. Subsequently, in either case, cancer reappears, *in situ*, and runs its course with rarely an exception to a fatal termination.

As compared with removal by the knife; the advantages of cauterization are, the bloodless character of the operation and, consequently, less exhaustion, and the less liability to erysipelas or pyæmia; the disadvantage is, the pain, severe and persistent.

The caustics employed are, the concentrated mineral acids, sulphuric or nitric, or the solid caustic alkalies,—potash or lime, and various chlorides, that of zinc especially. Of all these, the glacial sulphuric acid mixed with powdered saffron—forming a black paste, is preferred by Velpeau, particularly in fungoid and bleeding cancers. The caustic alkalies combined, form the well-known Vienna paste. The chloride of zinc

mixed with flour readily forms a paste by deliquescence. If a liquid caustic be used, the surrounding skin should be protected by a barrier of gutta-percha or other similar material attached to the skin. If chloride of zinc be used, the skin, which resists this agent, must previously be destroyed by sulphuric or nitric acid.

The depth to which the action of any such agent extends and the destruction of the tissues accordingly, will depend on the strength and quantity of the caustic employed. But the result can only be roughly estimated. The slough produced varies in appearance with the kind of caustic employed; a dry, hard, contracted blackish eschar, resulting from the application of a strong mineral acid; a wet pulpy slough, from chloride of zinc. It separates after a time, a few days to a month, disclosing a healthy granulating surface, but perchance, of prodigious depth and extent. Other modes of applying caustic have, therefore, been devised. The *repeated* introduction of chloride of zinc through incisions daily made deeper and deeper, affords a precaution for limiting the slough to the depth and extent of the cancer. This plan of treatment was first practised in this country by Dr. Fell, of the United States; a Report on which was drawn up by the Medical Staff of the Middlesex Hospital, in 1857. Another mode is to undermine a cancer with caustic, introduced through narrow passages pierced with a seton needle.

Of all these caustics and modes of their application, my own experience inclines to the chloride of zinc, which I first saw used by Mr. Liston about twenty-five years ago, and the efficacy of which has since been attested by its results in some cases.

In the ulcerated stage of cancer, disinfectants are requisite, for the double purposes of cleansing the sore, and of counteracting the effects of that peculiar fetor which would otherwise encompass the patient in a self-created poisonous atmosphere. Charcoal or yeast poultices, and lotions of chloride of lime or carbolic acid, are thus beneficial. I can speak favourably of the latter poultice and lotion. They were remarkably efficacious in the case of a large cancer springing from the arm and involving the shoulder. Ulceration having commenced in front of the axilla and subsequently, in other parts of the tumour; the odour would have been intolerable to the patient but for these appliances.

(b) *Congelation*.—The continued application of intense cold, is another means of destroying a cancer. Used in conjunction with caustic, congelation mitigates the pain, without diminishing the cauterization. Freezing is, alone, far less effectual. When most successfully practised, its destructive action extends not deeper than an inch; the only advantage then being the freedom from pain during and even after this process. As a method of treatment for cancer, it was introduced by Dr. James Arnott. Pounded ice may prove sufficient; but a mixture of ice, salt, nitrate of potash and hydrochlorate of ammonia, will freeze more thoroughly. The frigorific mixture should be circumscribed by gutta-percha or other pliant material, fashioned into a bowl around the part, with a tube to drain off the fluid as the mixture melts; and the process must be continued for some hours.

3. *Excision*, or *amputation*, for the *immediate* removal of cancer, is the treatment most worthy of consideration. Granting the local origin of cancer, and thence the subsequent infection of the system; excision—as distinguished from any *process* of removal—is indicated, and at the earliest possible period. Hence also amputation, where practicable,

may be preferable to excision—a partial operation, which may not thoroughly extirpate the disease. The delay of either operation, will assuredly allow the infiltrating course and adhesions of cancer to ensue, thereby rendering it locally impracticable or constitutionally useless.

These pathological considerations suggest certain general reasons in favour of both excision and amputation, and their comparative advantages.

(1) Extirpation of the disease, entirely and permanently. This is very rarely accomplished.

(2) Temporary removal of the disease, and thence a proportionate restoration of ease and health. This immunity is always gained.

The period of non-recurrence varies; perhaps less than one, it averages two years. Early performance of the operation may prolong this period to ten, fifteen, or twenty years. Such prolongation has been observed particularly in scirrhus affecting the breast. The experience of Velpeau and of Sir B. Brodie concur as to the long period of immunity which may be enjoyed.

(3) Prolongation of life. Comparing the duration of life in cases, without operation, and after: Mr. Paget states that, in the former case, the average period scarcely exceeds two years; whereas, in the latter, it extends to about twenty-eight months. Mr. Moore goes much farther, observing, that in 78 cases of cancer affecting the breast, not operated on, the average duration was 32·25 months; and in 57 such cases the average was 53·2 months. Any estimate of this kind is liable to a twofold error; the selection of cases for operation is generally those most favourable to life, and the probable mortality of the operation itself. The latter varies from 5 to 10 per cent.; and albuminuria peculiarly predisposes to a fatal issue. Objections with regard to each of the three foregoing considerations may be raised as to the propriety of operative interference, but the same objections apply with equal or greater force to any kind of treatment whatever, in the course of a disease so, apparently, irregular as that of cancer.

The conditions of cancer, or the cases which are respectively favourable and unfavourable for operation, may be stated, approximately, as follow; cancer of the breast being taken as the type:—

(a) *Favourable for operation.*—(1) A single tumour, not diffused, and whether in the nipple, on the surface, or in the substance of the breast. (2) When the nipple alone, or some portion of the skin, is drawn in towards the subjacent tumour. In either case, the superficial part not being widely infected but simply dimpled, the breast may be removed. But the disease is apt to return in and around the cicatrix. This took place in the case of a scirrhus breast which I removed in the condition described, a small portion of skin not larger than half-a-crown, being attached to the gland. (3) Ulceration of a cancerous tumour does not preclude operation, if in other respects the case be suitable. (4) The glands having become diseased to an extent which does not interfere with their removal, is a condition proportionately favourable for excision of the primary tumour. But the state of the glands cannot be exactly determined, otherwise than in the course of the operation, and if then found to be cancerous, they also must be removed; not necessarily, however, at that time, if such an enlargement of the operation might be perilous. Subsequently, and as soon as the health permits, the cancerous glands should be excised. This postponement I had recourse to in the case of a lady whose breast I removed for cancer; when the wound had healed,

I then removed the axillary glands—by a more limited incision than a continuation of the original operation would have involved. The disease eventually returned in the breast-cicatrix. (5) Amputation of a limb is justifiable, although the glands show some hardening or doubtful enlargement. This rule applies both to the encephaloid and epithelial disease. (6) Hereditary tendency, strongly manifested, does not entirely prohibit operation. In a family, of which six members were the subjects of cancer, one sister underwent excision of the breast in 1845, and another in 1846. Both remained well, until in each, with a recent recurrence of the disease, a second operation was performed in 1856—eleven and ten years after the primary operation. In 1859 both patients were alive. (7) Recurrent cancer may be removed under the same restrictions, as with reference to a first operation. My own experience of operation in such cases, is not favourable. In two—the original disease having been mammary cirrhosis—one or two only small button-like nodules reappeared in the cicatrix, these were at once removed, yet the disease speedily returned again. (8) Age does not prohibit the removal of a growing cancer.

(b) *Unfavourable* for operation.—(1) Certain constitutional conditions—*e.g.*, cancer co-existing, especially in some internal organ, or marked cancerous cachexia, albuminuria or other grave organic disease. (2) Diffused cancer and persistent œdema. But the latter condition is significant only when circumferential; œdema remote, depending on obstruction to the circulation at the seat of disease—*e.g.*, œdema of the hand from cancer of the arm, is not itself a prohibitive condition. In such case, I have seen the swelling subside and recur; apparently with varying states of the circulation as connected with the growth of the cancer above. (3) Adhesion, if at all extensive, either of the skin, or subjacent textures, is decidedly prohibitive of operation. (4) Ulceration, otherwise than to a very limited extent and depth, is equally so. (5) Cancerous tubercles in the skin over a cancer, is a condition even more unfavourable for operation. Over a mammary cancer, increasing thickness of the skin, its widespread adhesion, and enlargement of the pores; constitute a decisive contra-indication. (6) The glands having become diseased to an extent which interferes with their removal, prohibits also removal of the primary tumour, either by excision or amputation. (7) Rapid growth, in any way, is decidedly unfavourable for operation. Hence most encephaloid cancers are better left alone, unless in a very early stage. (8) Cancers, the relations of which to important parts around, cannot be foreseen, are better not meddled with. Thus circumstanced, are cancers beneath the scalp, which often implicating the bone, penetrate the skull; cancer of the eye, which often involves the optic nerve; cancer of either jaw, particularly the upper, where it is apt to protrude into the maxillary sinus or the ethmoid cells; and cancers about the root of the neck. I once assisted my colleague Mr. de Méric in removing an encephaloid cancer situated about the sixth rib, below the fold of the pectoral muscle on the right side. The tumour was not larger than an orange, the skin unbroken, and it seemed moveable on the rib. Yet, on commencing the operation, the hæmorrhage was alarming, the rib gave way, and any further attempt was at once discontinued. The man, of florid complexion, became blanched with almost fatal syncope in a moment, and rallying only for a short time, he died of internal hæmorrhage; a warning in all such, and similar cases.

**EPITHELIAL CANCER.**—One *variety* of cancer I have reserved for special description; because, although in many points allied to encephaloid and somewhat to scirrhus cancer, it nevertheless presents very characteristic appearances, and possesses much surgical interest. I allude to epithelial cancer.

*Structural Condition and Diagnostic Characters.*—This variety consists essentially of cells or scales, resembling those of scaly epithelium, infiltrated among the component elements of the skin or mucous membrane, or sometimes among the textures of internal organs. Whatever portion of the skin or mucous membrane may be thus affected, the epithelial cancer-cell or scale has very much the same characters. (Fig. 27.) It is flattened, of an irregular outline, with usually a prolonged diverticulum

FIG. 27.\*

at some point of its margin, and of a variable size. It contains pale molecular matter, converging towards a central nucleus, which is clear, bright, and well-defined, round or oval, and very small in comparison with the cell; more uniform also in its shape and size. This nucleus is usually single. It may contain two or more minute granules, but rarely a bright distinct nucleolus.

Associated with these cells, are what Paget calls "brood-cells," or endogenous cells. They present many varieties of appearance, which may be regarded as the results of one or more nuclei, enclosed within cells, assuming, or tending to assume, the characters of nucleated cells.

The "laminated capsules" of Paget—"globes épidermiques," Lebert—are the most singular and characteristic structures of epithelial cancer, yet not peculiar to this disease; nor are they, apparently, special structures, for they consist of epithelial scales. These capsules are very large and spherical cysts, containing granular matter, nuclei, or cells, obscurely seen within them; and clustered so as to almost appear as if fused together; but each capsule consists of epithelial scales, superimposed in successive layers, thus forming a laminated capsule.

Such are the structural elements of epithelial cancer. They are found infiltrated—principally in the substance of the skin or mucous membrane—but not uniformly diffused throughout the component textures of the part affected.

The cancer-cells may predominate in the corium, forming a swelling very slightly elevated above, or imbedded below, the proper level of the integuments, and the depth or thickness of which is much less than its dimensions laterally; or these cells may predominate in the papillæ, presenting a prominent warty or exuberant out-growth; or, the sub-integu-

\* Epithelial cancer-cells or scales in various forms. Magnified 350 times. (Paget.)

mental texture may be their chief seat, forming a deeper-seated, flat or rounded mass.

Of these varieties, the first two may be named the *superficial* or *out-growing*; while the third is the *deep-seated* form of epithelial cancer. Paget believes that either of these principal varieties may occur in any of the usual seats of this disease, but that they are not both equally common in every such part. The superficial, and especially those which have the characters of warty and cauliflower-like out-growths, are most frequently found on mucous membranes, especially of the genital organs; those also on the extremities and the scrotum have usually a well-marked warty character, and are rarely sub-integumental. The deep-seated are more frequent in the tongue than elsewhere.

It must not be forgotten, however, that these distinctions are more *apparent* than *essential*. Their value consists in reference to the earliest and most exact diagnosis of this disease, in whichever form it may chance to make its first appearance. For subsequently, and especially when ulceration has commenced, an epithelial cancer which was superficial or exuberant, is prone to extend into deep-seated parts; and one at first deeply-seated may grow out exuberantly. Moreover, when ulceration is progressing, a greater uniformity of external appearance is found; because, in general, while all that was superficial or exuberant is being destroyed, the base of the cancer is constantly extending, both widely and deeply, into the sub-integumental tissues.

Respecting, then, the *earliest* appearances of epithelial cancer, the following are most diagnostic.

1. Of the *superficial* or *out-growing*, prior to ulceration, they are these:—

(a) An *outspread* swelling arises—say on the lower lip, labium, pudendi, or scrotum; and an unnatural firmness or hardness of the affected

FIG. 28.\*

skin is perceptible; but the superficial dimensions much exceed the

\* Epithelial cancer of hand; showing the papillary character, from specimen in the Museum of St. Bartholomew's. (Ser. x. i. 6.) The history of this case is in Pott's Works by Earle, iii. 182. The patient was a gardener, who had been employed in strewing soot for several mornings. The disease was of five years' duration. (Paget.)

thickness of this swelling. Its outline is round, oval, or sinuous; and its surface, sometimes nearly smooth, is more often coarsely granulated—like that of a syphilitic condyloma—deriving this appearance from the enlarged and closely clustered papillæ. Generally, the surface is moist with an ichorous discharge; it may, however, be covered with a scab, or encrusted with a soft substance, consisting of detached epithelial scales. In most cases, the part is unduly sensitive, and injected with blood. If the papillæ become infiltrated, they constitute the *cauliflower*-like mass so characteristic of the ordinary form of epithelial cancer. (Fig. 28.) This mass looks very vascular, is moist with ichor, and covered with pasty cakes of epithelial scales, which beset the interstices of the enlarged papillæ.

(b) Occasionally, the shape of an out-growing epithelial cancer is that of a *sharply bordered circular or oval disk*, upraised a little above the level of the adjoining skin, or mucous membrane, and imbedded to about the same depth below it. The surface of this disk—usually flat or slightly concave—is granular, spongy, or irregularly cleft; and its margins are surrounded with healthy texture, which becomes raised and often slightly everted by their enlargement—*e.g.*, many epithelial cancers of the tongue.

(c) Sometimes, epithelial cancer grows out in the form of a *cone*.

(d) Lastly, the out-growing form of this disease may be a *narrow-stemmed*, and possibly pendulous, growth from the skin.

These and other shapes of superficial epithelial cancer resemble somewhat the appearances presented by warty and condylomatous growths; but they differ essentially in respect of their minute structure;—being infiltrations of the skin and papillæ with epithelial cancer-cells; whereas the structure of warty-growths remains healthy, however strange may be the appearance they assume.

2. Deep-seated epithelial cancer is generally (a) an *advanced stage* of the superficial; for by progressive infiltration, the subcutaneous or sub-mucous tissues are invaded; (b) but this variety of the disease may occur *primarily*, although comparatively rarely. “Thus,” observes Paget, “the first formation of epithelial cancer may be in masses of circumscribed infiltration of the tissues, beneath healthy skin or mucous membrane.” This condition is more frequent in the epithelial cancers that form, as recurrences of the disease, near the seats of former operations, or as secondary deposits about the borders of primary superficial growths.”

*Situation*.—Epithelial cancer selects either the skin or subcutaneous texture; or the mucous membrane; and of these textures the portions most liable are ranged by Paget in the following scale of frequency. First, its chosen seat is the *lower lip*, at or near the junction of the skin and mucous membrane; then the *prepuce* (glans, Rokitansky), *scrotum* of chimney-sweeps; the *nymphæ*, the tongue; more rarely in very many parts; as at the anus, interior of the cheek, upper lip, mucous membrane of the palate, larynx (trachea, Rokitansky), pharynx and “cardia;” neck and orifice of the uterus (stomach, Rokitansky), rectum, and urinary bladder; skin of the perineum, of the extremities; the face, head, and various parts of the trunk. In more rare instances, as a primary disease, it occurs in other than integumental parts; as in the inguinal lymphatic glands, in bones, in tissues forming the bases or walls of old ulcers. Rokitansky has met with epithelial cancer only once in a parenchyma—namely, in the liver, and then encysted in a capsule of fibro-cellular

tissue. By extension from its original seat, this growth may involve many deeper textures; fascia, muscles, bones; and as a *secondary* disease may, but very rarely, supervene in internal organs—the lungs, liver, and heart.

Epithelial cancer, as a primary disease, is usually *solitary*. Occasionally, two or more co-exist, and even in the same part, as on the prepuce and glans. Eventually, secondary epithelial cancer-growths may form in the tissues surrounding the primary and parent growth.

*Course*.—The *ulcerative* stage of epithelial cancer is that in which the disease is usually seen; and the usual state of ulceration observed is that of progressive destruction of the central and superficial parts of the cancer, with more than co-extensive growth of the marginal and deeper parts, thus constituting the type of the “cancerous ulcer.”

It is important, therefore, to be able to discern the *first* aspect of ulceration—both as regards the superficial and the deep forms of epithelial cancer, respectively; and then, the characters of the complete ulcer.

1. Ulceration of *superficial* or out-growing epithelial cancer, primarily appears as either a diffuse excoriation of the whole surface of the cancer, except its borders; or else a shallow ulcer limited at first to some fissure where the disease commenced. The discharge from this excoriated or ulcerated surface usually dries into a thin scab, or a thicker and darker crust; which conceals for a while the ravages of ulceration, still slowly extending beneath,—downwards and outwards.

2. Ulceration of *deep* epithelial cancer begins in one of three ways:—

In some cases, the superimposed skin or mucous membrane having become adherent and thin, cracks; and this condition may remain stationary for a long while, in the form of a dry dark crevice; but usually ulceration, commencing from this point, extends into the mass of the cancer.

In other cases, the substance of the cancer having become inflamed, it softens, suppurates, and discharges its contents through an ulcerated opening, or a long rent; leaving a cavity which speedily assumes the characters of an ulcer, and extends peripherally.

In a third series of cases, and, perhaps, especially in secondary formations, and in those under the scars of old injuries, the cancer protrudes through a sharply bounded ulcer in the sound integument or scar, growing exuberantly, with a soft shreddy surface, like a medullary cancer, or with a firmer, warty, or fungous mass of granulations.

Dissimilar as are the earliest aspects of ulceration in both forms of epithelial cancer,—out-growing and deep, they gradually assume an uniformity of appearance which is very characteristic.

3. *Complete Ulcer*.—An excavated sore, of a round or oval shape, presenting a roughly granular surface, which has a brick-dust red colour, and oozes a stale-smelling discharge. This surface bleeds easily, although not freely. The textures surrounding its base and borders become indurated and rigid, as they progressively become more and more infiltrated with cancer-cells. The ulcer thus acquires a remarkable degree of immobility, and its margin protrudes in the shape of a thick everted ridge, well defining the boundary of the ulcer. Infiltration increasing, the marginal ridge forms an irregular nodular belt, which overhangs the base of the ulcer and gives an undermined appearance to its everted borders. If the *papille* of the surrounding skin are more particularly the seat of cancerous infiltration, then a warty rather than a nodular belt

springs up around the ulcer. With all these signs of progressive infiltration, followed by ulceration; the work of destruction is not stayed below the *base* of the already excavated sore. It spreads deeper and deeper, sparing no texture, not even large arteries, which hold out against the invasion of most other forms of ulceration, if indeed they do escape altogether. But arteries of the first magnitude yield to the unsparing ravages of epithelial cancer.

*Affinities to Cancer.*—There are good and sufficient reasons for regarding this disease as a *variety* of Cancer. Its infiltrating character as a growth, is the essential guarantee of identity; while, its indiscriminate invasion of all textures, its ulcerative tendency, and unsparing destructiveness, corroborate the malignant nature of this growth. Then again, the lymphatic glands are early liable, although not prone, to become affected by the continued epithelial infiltration of the primary growth; but secondary formations thence arising are almost exclusively limited to glands in connexion with the immediate vicinity of the primary disease. A similar epithelial form of growth, or more commonly encephaloid cancer, may however secondarily spring up, indiscriminately in parts distant from the original disease; and there is also the less significant fact of recurrence, sooner or later, after removal by operation. Lastly, in point of hereditary influence, members of the same family, in whom either scirrhus or encephaloid cancer occurs, are peculiarly liable to the epithelial form of growth. Duly weighing all these affinities, singly and collectively, this epithelial growth is rightly denominated *epithelial cancer*. In this conclusion the most able pathologists concur; Rokitsky, Virchow, Paget, and others.

Epithelial cancer must not be confounded with the “Epithelioma” of Hannover and Bennett, who include under that title many other growths besides this variety of cancer; and it differs also from the “canceroid” of Lebert.

*Treatment.*—The guiding indications of treatment in respect to epithelial cancer, are two; one or other of which is always practicable.

(1) To superinduce inflammation and sloughing, thus destroying the cancer. This may be accomplished by caustics; such as those already mentioned for the destruction of cancer generally; the strong mineral acids, caustic alkalies, and chloride of zinc. But it must be confessed that this method of treatment is not more successful in the one case than the other. In one instance, of an encephaloid cancer of the entire circumference and nearly the whole length of the vagina, I repeatedly applied the strong fuming nitric acid by means of a glass brush; but without apparently any effect, for better or worse.

(2) Removal of the cancer is the most effectual treatment. This may be accomplished by excision, ligature, or amputation.

The former method is, generally, most eligible; care being taken to cut sufficiently wide for the entire extirpation of the growth. It will be necessary to include any neighbouring lymphatic glands which have decidedly become, secondarily, affected by the cancerous infiltration. But the strong infiltrating tendency of epithelial cancer renders its effectual removal by excision doubtful. Removal by ligature, or the eraser, is the alternative method; wherever excision is impracticable, or would be imprudent, or inefficient.

Amputation is necessary, primarily or secondarily, in certain cases. It may be so, in the first instance, owing to the extent of the disease, or

its locality, as when situated on the leg, or the arm, near the trunk. Of the latter urgency for amputation I had an instance in the case of an epithelial cancer just below the shoulder joint. [P. p. 633.] The patient died, after the operation, of Hospital gangrene. Secondary amputation is unavoidable in any case of recurrent-cancer; caustics, excision, ligature, or even primary amputation, as the case may be, having failed, perhaps successively, to extirpate the primary disease.

### CHAPTER III.

#### DEGENERATIONS.

To clearly understand the significance of the term degeneration, it is necessary to bear in mind the nature of healthy nutrition, of which physiological process, Degeneration is only another modification,—concluding the Pathology of Nutrition.

The functions of the various organs and parts of the body, in health, are so adapted or adjusted as to constitute an evenly-balanced living organization. And this co-operation is continued throughout life, in health. But the activity of all the functions—nutrition, for example—varies materially, during the successive periods of existence.

After birth and with an independent existence, during infancy, youth and adolescence to maturity; the function of nutrition is yet more one of *growth* and development. During mature manhood or womanhood, this function is simply one of *maintenance*, to repair the muscular waste of the body consequent on the functional exercise of its various members and organs. Lastly, as age approaches, and during decrepitude, the nutritive power of the body proportionately declines. Waste is still repaired; but the textural structure reproduced is an imperfect representation only, not a copy, of either its original or mature condition; it is a *retrogression* of textural structure, effected by a *degenerative* modification of nutrition. Degeneration is, therefore, only the concluding stage of the natural course of healthy nutrition, and as the concomitant retrogression of textural structure extends more or less throughout the body, and certainly pervades vital organs, the whole organism retrogrades or reverts to the unorganized matter whence it came. Earth returns to earth, ashes to ashes, dust to dust. To die by degeneration is, therefore, as natural as to live by growth and development, and by the subsequent maintenance only, of nutrition. This function is, indeed, the consummation and resultant of all the other organic functions; and when in the order of nature they decline, nutrition declines also into degeneration, which it then represents. But this ultimate modification of nutrition is sufficient for life as age advances, all other functions declining simultaneously and proportionately.

The *senile* retrogression of textural structure, thus effected, cannot, in any sense, be designated a diseased condition, nor the result of any morbid process. Nor again, when degeneration, natural to advancing and advanced life, occurs *prematurely*, can it then be regarded as a morbid process of nutrition, issuing in a diseased condition of textural structure. It is only premature old age; but the individual overtaken by degenera-

tion is the subject of *defective* nutrition, and in this sense only, retrogression of textural structure by degeneration ranks, and may be classed, with morbid products of Nutrition.

Degeneration, whether senile or premature, is a form of atrophy; but it is so by a deterioration of structural quality, not by a mere diminution of quantity. And, be it observed, this structural deterioration is effected by the relapse or falling back from a higher condition to a lower or more elementary grade of textural structure or even to an altogether structureless condition. It, moreover, takes the place of or substitutes the proper elements of the original texture, which concurrently disappear.

This *relapse* and *substitution* of textural structure, are the essential characteristics of Degenerative transformation. By substitution, it is distinguished from the transformation of texture resulting from another and widely different cause,—Disintegration.

*Causes.*—Analogy and facts alike concur to render the conclusion highly probable that degeneration, as being a modification of nutrition, is caused primarily by an appropriate blood-disease, in regard to each kind, of which it is the local and anatomical manifestation.

On the other hand—as Mr. Paget observes—degeneration, like simple atrophy of quantity may arise from local causes, and apparently the same such causes; namely, diminished supply of arterial blood, as by partial closure of the chief nutrient artery of the part; or by abrogation or suspension of function. Furthermore, both degeneration and atrophy occur commonly in old age, but possibly prematurely; both also may occur simultaneously in one and the same texture, under precisely the same conditions; and, a cause of atrophy in one case may cause degeneration in another. In relation to disease, both may concur, as in inflammation; or the disease, so called, may be only degeneration, as in simple softening of the brain or spinal-cord, and the liquefaction of inflammatory exudations during the suppurative process.

*General characters of Degeneration.*—1. The new material is of lower chemical composition;—*i.e.*, less remote from inorganic matter, than that of which it takes the place. Thus, fat is lower than any nitrogenous organic compound, and gelatine lower than albumen, and earthy matter lower than all these.

2. In structure, the degenerate part is less developed than that of which it takes the place: it is either more like inorganic matter, or less advanced beyond the form of the mere granule, or the simplest cell. Thus, the approach to crystalline form in the earthy matter of bones, and the crystals in certain old vegetable cells, are characteristic of degeneration; and so are the granules of pigment and of many granular degenerations; and the globules of oil that may replace muscular fibres or the contents of gland-cells, and the crystals of cholesterine that are often mingled with the fatty and earthy deposits.

3. In function, the part has less power in its degenerate than in its natural state.

4. In its nutrition, it is the seat of less frequent and less active change; and without capacity of growth, or of development.

*General Treatment.*—The pathological indications of treatment, in regard to degeneration, are two:—

1. To elevate the condition of degeneration to some higher state of textural structure. This indication cannot be fulfilled by any known Hygienic or Therapeutic measures. The practicability of effecting

recovery from degeneration would seem to be inconsistent with the vital incapacity of a degenerate part for growth or development.

2. To counteract any further degeneration in an already degenerate part, or its extension to texture continuous. This indication may, perhaps, be accomplished by Hygienic and Therapeutic measures, either of which are general or topical. It would appear that whatever influence, of a preventive character, any such measures may have; their action is mainly through the medium of the blood, by raising its quality and promoting its circulation.

*Hygienic* measures, of a counteractive character, are, in general, such as have reference to the functions concerned in blood-production. Diet, selected with regard to the particular form of degeneration; pure air, friction of the skin, shampooing, baths warm or cold, regular exercise, and other means of promoting excretion, are thus highly important.

*Medicinal* measures, within the present range of therapeutics, are less obviously counteractive of degeneration. Iron, cinchona bark, the mineral acids, and other tonics, may have some beneficial influence, by improving the quality of the blood and invigorating the circulation; while aperients, diaphoretics, and diuretics, increase and regulate the excretions of the bowels, skin and kidneys. Some such resources are found in convenient, and apparently inimitable combinations, in the various natural chalybeate and saline mineral waters of Vichy, Wiesbaden, and other Spas. In such resorts, persons of "a broken or worn-out constitution"—subjects of degenerative changes of structure—experience a temporary revival of their failing powers, if not a permanent restoration to health.

Rarely, any topical applications are beneficial; degeneration, of any kind, affecting internal organs, scarcely being influenced by such treatment.

*Special Kinds of Degeneration.*—Pathologists differ as to the number and specific distinctions of the various kinds of degeneration. The classification of Paget is not that of Dr. J. Hughes Bennett; nor this again, that of Dr. C. J. B. Williams.

As this branch of Pathology stands at present, I would propose the following arrangement:—(1) Fatty degeneration; (2) Pigmentary; (3) Fibrous; (4) Amyloid? Waxy, or Lardaceous; (5) Granular; (6) Calcareous, osseous, or mineral degeneration.

These various forms of degeneration are of much pathological interest to the student in Surgery, as well as in Medicine; and it is a subject upon which, respecting Fatty degeneration in particular, I have made a series of microscopic observations, both in animals and the human species. But, the distinctive structural and physical characters of each form of degeneration, and as taking place in the various normal Textures, new Products, as of Inflammation, and in Morbid Growths, are fully described in my work on "Principles;" and, as such degenerative transformations are little amenable to any special treatment—in addition to the general indications already noticed—it would be of insufficient practical importance to here re-describe them.

## CHAPTER IV.

## ULCERATION AND ULCERS, GANGRENE AND MORTIFICATION.

DEATH of any part of the body, as contrasted with its nutrition, is essentially a disintegration of the constituent elements of structure and resolution into molecular matter; the destruction of the organization which resulted from development; the falling to pieces of that which the formative power had constructed. Disintegration, like Degeneration, therefore denotes both a process and its result in the destruction of structure.

Disintegration is related to Degeneration: the latter presupposes the former, but conversely, the former does not necessarily presuppose the latter; for Disintegration may occur independently, without any preceding Degeneration of texture.

Ulceration, and Mortification including Gangrene, are essentially processes of Disintegration and textural death. But the pathology of these processes, and their difference in degree only, should be clearly understood.

ULCERATION.—A disintegrative process, essentially; the molecular matter resulting from ulceration may disappear in either of two ways:—

Firstly.—By discharge, in the liquid form; thus leaving a chasm or *ulcer*.

Secondly.—By absorption through the lymphatics and veins jointly, especially the former vessels; thus leaving a chasm or ulcer. “Ulcerative absorption” of Hunter.

Possibly, both modes of removing the disintegrated textures co-operate in ulceration.

The *evidence* in support of each such aspect of its pathology, is fully considered in the other work. [P. p. 513 *et seq.*] The balance of evidence is, I think, decidedly in favour of the removal of the disintegrated matter by discharge. This matter can, indeed, be *seen* to come away occasionally; the molecular matter accumulating in the form of minute sloughs, whenever disintegration proceeds too rapidly for its discharge in the liquid form; and again disappearing as molecular matter, when disintegration and discharge proceed evenly.

*Degeneration* precedes the disintegration consequent on inflammation; and probably, therefore, precedes ulceration. The degeneration connected with inflammation, is usually fatty. Thus, it takes place in muscles, as shown by Virchow's observations, and perhaps in muscular tissue of the involuntary order—*e.g.*, the heart, as in a case of fatal traumatic pericarditis examined by Mr. Paget; in bones, in the liver, and the kidneys, as shown also by Virchow; in the cartilages, as noticed by Redfern; and in the cornea, by Strube. Calcareous degeneration may be the prior textural change. It takes place in chronic rheumatic arthritis; with inflammation of the laryngeal cartilages; and the formation of imperfect dentine, with inflammation of the tooth-pulp, is, perhaps another illustration.

The proper discharge from an ulcer—the product of ulceration, not that of a granulating sore—is ichor, the nature of which is not well understood.

*Ichor*, is usually a thin sanious fluid, colourless or slightly yellow; structureless, but mixed with exudation, pus, and blood corpuscles, and with the disintegrated matter or *débris* of the textures. Its chemical composition, as to the essential constituents of this fluid, is unknown. Its chief property is corrosiveness; the operation of ichorous discharge maintaining and extending ulceration.

*Diagnostic Characters of Ulcers.*—An ulcer differs widely in appearance. Ulceration forms a chasm of very variable extent and depth, from the slightest abrasion of the integument to the deepest cavity down to and into the bone; it is found less frequently as such, than accompanied with granulations of some description, overspreading the whole or part of the surface. The circumferential margin of the ulcer varies in thickness, and in direction; being turned inwards and perhaps undermined, everted, irregular, or tolerably even; its colour and that of the surface may be red, dusky brown, livid, or otherwise shaded; while the ichor or discharge varies greatly in quantity and quality from the typical characters already stated, through every description of mixed discharge, or even healthy pus.

All these different appearances proceed, generally, from constitutional conditions; but, occasionally, they are produced by external causes acting locally on the part; as by friction, filth, or various topical applications and dressings.

Two classes of ulcers, therefore, each including subordinate varieties, might be recognised with reference to their pathological origin; but, practically, it may be difficult to draw this line of distinction. Hence the distinctive species and varieties of ulcers are differently enumerated by authors; the nomenclature also differing accordingly. The following species present, perhaps, the most distinctive characters:—

(1) Healthy or typical Ulcer. (2) Inflamed. (3) Irritable. (4) Œdematous. (5) Indolent, and Varicose. (6) Phagedænic. (7) Hæmorrhagic. (8) Scorbutic. (9) Scrofulous. (10) Cancerous. (11) Lupoid. (12) Syphilitic.

(1.) **HEALTHY OR TYPICAL ULCER**—consequent on a wound or other injury, or the separation of a slough; an open sore thus formed, in a healthy person and itself in a healthy state, presents certain characters, of variable extent, depth, and shape; the *surface* is uniformly mammillated with small florid granulations; which, however, do not bleed readily and are not painfully sensitive. Healthy *pus*, opaque, yellowish, and of creamy consistence, more or less in quantity, bathes this granulating surface. The *margin* of such an ulcer shelves gently down to its base, and is scarcely perceptibly harder than the adjoining healthy skin. The new skin, corresponding to the margin, has an opaque white colour, and its formation is preceded by a linear translucent film of cuticle, which, veiling the subjacent granulations, has a bluish-white tint. The granulations immediately within this line are more florid than those nearer to the centre of the ulcer, because more vascular where the cuticle and skin circumferentially, are being formed.

The surface having reached the level of the skin, by granulation, and the formation of pus,—superfluous organizable material,—having ceased; cicatrization proceeds inwards by the continued formation of marginal

skin, preceded by cuticle, and thus, at length, presents the characters of healthy cicatrix, in the recent state. [See Reparation by Granulation.]

*Treatment.*—Little or no positive treatment is requisite, a healthy ulcer healing spontaneously, provided any circumstances adverse to the process of reparation be excluded. Rest, position, to prevent tension and any undue determination of blood, and protection of the surface by water-dressing; are sufficient.

(2.) INFLAMED ULCER.—A departure from the healthy type of ulcer; the usual signs of inflammation are characteristic. An area of redness with some swelling around the ulcer are more or less conspicuous appearances; while a burning heat and aching pain are experienced, particularly when the part is pendent, as the shin, a common situation for an inflamed ulcer. The granulations have a rose-red rather than a florid colour, or they may be absent and the surface of the ulcer overspread with a thin ash-grey slough; the suppuration is scanty, thin, and perhaps tinged with blood. As inflammation subsides, the cuticle peels off or desquamates for some distance around the ulcer.

This condition of sore accompanies inflammatory fever, an ulcer previously healthy then becoming inflamed; or it may be produced by external violence or consequent on local irritation.

*Treatment.*—Any cause or causes in operation will, as usual, primarily direct the treatment, namely, their removal. Then, remedial measures are those appropriate for inflammation. A poultice, or a cold evaporating lotion, if more agreeable, and perhaps the local abstraction of blood by a few leeches applied in the neighbourhood of the ulcer; with rest and an elevated position of the part, and, finally water-dressing as the sore assumes a healthy character and undergoes the process of healing. Bandaging the limb, may, at this period, be useful to support the weakened vessels of the part, and thus prevent any liability to the continuance or recurrence of a low state of inflammation; a very troublesome chronic condition, which is apt to follow an acutely inflamed ulcer.

(3.) IRRITABLE ULCER.—This variety of ulcer is to be distinguished from an inflamed ulcer, with which it might be confounded. Painful to a degree, even of a neuralgic character, the other and more peculiar signs of inflammation, particularly circumferential redness and swelling, are wanting. The granulations are imperfect, or absent, reddish here, tawny there; but they are very painful and sensitive to the touch, and readily bleed on slight pressure or the application of a stimulant dressing. The discharge is thin and sanious; and the edge of the ulcer, irregular, sharp, and abrupt, evincing no disposition—not to say an obstinate indisposition—to commence cicatrization.

Commonly situated on the shin or lower part of the leg; an irritable sore or fissure of the anus not unfrequently occurs, which well illustrates the pain and other characters of this variety of ulcer. It is generally connected with some disturbance of the digestive organs, and with constitutional irritation as distinguished from inflammatory fever. More rarely, some cause of local irritation may co-operate: as the passage of the fæces and the contraction of the sphincter-ani muscle with regard to irritable ulcer in ano.

*Treatment.*—The removal of any cause in operation is the primary consideration. Hence the rectification of the constitutional disorder, by saline purgatives and mercurials to influence the secretion of bile. Then, opiates occasionally, will do much to allay the general irritability. Of topical

applications, nitrate of silver freely applied is the most efficacious. Lead and opiate lotions may also be recommended. Rest of the part is necessary or advantageous, as in the treatment of other ulcers; and thus, division of the sphincter-ani muscle by incision through a fissure of the anus, will relieve pain and facilitate granulation in that situation. In any case of irritable ulcer, as healthy granulations spring up, the pain subsides; and the cicatrix formed is not more than ordinarily sensitive.

(4.) EDEMATOUS ULCER.—In this variety of ulcer, the granulations are large, pale, translucent and flabby, sometimes cropping-up as large gelatinous masses above the level of the sore. The discharge is watery, and the margin has no disposition to commence cicatrization. Indeed, the granulations are apt to slough. This condition arises in connexion with a weak circulation, or it may proceed from the soddening of an ulcer by continued poulticing or other prolonged application of moisture and warmth.

*Treatment.*—In addition to the removal of any constitutional or local cause; local treatment is often remarkably curative. An elevated position, astringent lotions, as of sulphate of zinc or nitrate of silver, and the support of a bandage; will probably succeed in reducing the granulations to the level of the ulcer, when exuberant, and strengthen their vitality, thus favouring cicatrization.

(5.) INDOLENT, AND VARICOSE ULCER.—A deep and, perhaps, large excavation, presenting a flat surface,—without granulations, of a dusky or pale colour, scarcely sensitive to the touch nor disposed to bleed, and having a firm, hard base adherent to the subjacent fascia. A thin offensive discharge exudes. The edges are everted, thick, and callous, and of an opaque-white colour,—owing to accumulated epidermis; the surrounding integument to some distance being congested, of a dusky hue, and pigment stained, thickened, hardened, and bound down to the textures beneath. Such an ulcer is obstinately indisposed to heal. It is commonly situated on some part of the leg.

An ordinary—non-specific—indolent ulcer does not seem to be dependent on any constitutional disorder; but it is apt to occur in weakly, ill-nourished, and perhaps ill-fed persons.

The *varicose* ulcer, is a variety of indolent ulcer, and so named from its connexion with a varicose condition of the adjoining veins. Resembling generally an ordinary indolent ulcer, it differs in certain tolerably distinctive characters. Situated on some part of the leg, commonly on the inner side towards the ankle, and single; in the recent state it is of small size, ovoid shape, and with its long axis in the direction of the limb: without granulations and firm, a bluish-purple colour of the base and more so of the margin and surrounding integument, is conspicuous, and the ulcer is not unfrequently painful and sensitive. Inflammation and sloughing, or other conditions, may temporarily veil these appearances; but the tortuous, knotty enlargement of the venous trunks, or the more diffused mottling of smaller varicose veins, with, perchance, a brownish-red pigment stained skin around the ulcer, is still a characteristic accompaniment. In the progress of varicose ulcer, an occasional event of practical importance is venous hæmorrhage; arising from the ulceration having penetrated an enlarged vein, it may occur suddenly and copiously.

*Treatment.*—An indolent ulcer cannot cicatrize so long as it and the surrounding integument are both bound down; the margin being upraised and retracted, and the base depressed. Accordingly, pressure

and stimulation conjoined, represent the plan of treatment. The nitrate of silver freely applied to, and around the ulcer, or the continued application of zinc ointment, with tolerably firm bandaging may bring it into a healthy condition. A more even and constant pressure is secured by strapping the limb with strips of linen spread with soap-plaster, mixed with a little adhesive plaster to fix it. Drawn around the limb, from the side opposite the sore, each strip in succession should partly overlap the preceding one, and the ends be crossed obliquely; thus forming a compact caseament, and which should extend two or three inches above and below the sore.

Blistering circumferentially, softens and loosens the integument, and may thus tend to facilitate cicatrization. Incisions have been recommended to allow the granulations to contract; and, in most obstinate cases, transplantation of a portion of adjoining healthy integument, sufficient to close in the ulcer, may be tried; with the view of forming a substitute-cicatrix. Of these three resources, I am decidedly in favour of blistering.

Opium seems to have some special influence in rendering the granulations florid, and promoting the healing of an indolent ulcer. It is therefore, advisable to keep the system under this influence by the repeated administration of opium, in small doses. Stimulants, tonics, and a generous diet, will often prove beneficial.

The *varicose* ulcer is amenable to the same plan of treatment; but the varicose state of the veins, as the cause in operation, is an additional and the special object of treatment. An elevated position of the limb to relieve congestion, and an elastic bandage or stocking to equally support the vessels, will prove sufficient for this purpose, in most instances. When the ulcer has healed, it may still be necessary to wear an elastic stocking, as a preventive measure. In more obstinate cases, and with the view of a *permanent* cure; obliteration of the larger veins may be resorted to. Of the many means devised, the safest and most successful, in my experience, is the following:—A hare-lip pin is passed underneath the vein, and another at a point about an inch distant. Care must be taken that the vessel be not transfixed, a misadventure easily avoided by dipping the pin, and readily discovered by the escape of a drop or two of venous blood. If the vein be transfixed, the pin should be withdrawn and introduced at another point. A ligature passed round either pin in a figure of eight fashion, will compress the vessel sufficiently to cut off all communication with the venous blood in either direction, and thus isolate the portion of vessel between the pins. Division of the vessel in that situation subcutaneously, as recommended by Mr. Lee, will then more thoroughly ensure its obliteration. (See VEINS.) Several such interceptions may be necessary at different points in the course of the saphena vein; in which case the highest pair of pins should be introduced first. The pins must be allowed to remain for about a week. I do not find the tendency to slight ulceration of sufficient importance to require the precaution generally recommended, that of protecting the vein with a piece of bougie before applying the ligature. After this operation, in no case have I seen any perilous consequence, such as phlebitis or pyæmia, but diffuse or erysipelatous inflammation ensued for a while, in one case. In some instances, after the lapse of a year and a half or two years, occlusion of the vein has still been complete, a permanently successful result which has allowed of active exercise with comfort; in other cases, the

varicose condition has returned, as the only unfavourable issue; while in yet a few, it has remained on the removal of the pins, and a repetition of the operation has altogether failed.

Venous hæmorrhage, occurring in the course of a varicose ulcer, may be arrested by a compress of lint, secured by a bandage, over the aperture in the vein which has given way; and by elevation of the limb.

(6.) PHAGEDÆNIC ULCER.—Essentially a spreading ulcer, it is characterized by dusky red discoloration and swelling, with perhaps acute pain around the ulcer; a grayish, glutinous or slimy slough, which exhales a peculiar fætid odour, occupies the surface of the sore, and the edges, sharp, irregular as if worm-eaten, and undermined, fall away rapidly; thus enlarging and deepening the area of the ulcer. Sloughing may predominate in such ulceration, and hence sloughing and phagedænic ulcers are not uncommonly associated.

Sooner or later, constitutional disorder ensues; irritation rather than inflammatory fever, with great weakness and exhaustion.

Allied as this condition is, in its local and constitutional characters, to Hospital gangrene; it would seem that such gangrene arises from an external cause,—contagious matter applied to a sore; the constitutional disorder being secondary and symptomatic, although in its turn affecting the ulcer. On the other hand, habitual deprivation of food, the abuse of stimulants, or living on spirits, and, perhaps, overcrowding, with destitution; seem to give rise to phagedæna.

*Treatment.*—To arrest the rapidly spreading ulceration, a free application of strong nitric acid, by means of a glass brush, is most effectual. Followed by poultices, the slough, thus formed, is detached, exposing probably a healthy surface, which has acquired a healing character. Re-application of the acid may be necessary, or the continued application of yeast, charcoal, or chlorinated poultices may be sufficiently stimulant and cleansing; and, at the same time, disinfectant. Opium, administered in small and repeated doses, so as to keep the system under its influence, is most potent in allaying the irritative fever; while the strength of the circulation and healthy nutrition, are restored by quinine, the mineral acids, and a generally nourishing diet.

(7.) HÆMORRHAGIC ULCER.—Any variety of ulcer may assume this character, but some more particularly—*e.g.*, the irritable, phagedænic, varicose, cancerous, and, perhaps, lupoid ulcers. by the penetration of a blood-vessel; and the scorbutic ulcer, by passive hæmorrhage owing to the blood-condition. Not unfrequently, an ulcer oozes blood about the catamenial period, and especially in women suffering from amenorrhœa; the hæmorrhage then being vicarious menstruation. An ulcer thus acquires a bloody, clotted appearance.

*Treatment.*—Arising from such various causes, an hæmorrhagic ulcer is a contingency rather than any special variety of ulcer,—and should be treated accordingly in connexion with whatever ulcer it may be associated; by reference to the particular condition, local or constitutional, which causes the hæmorrhagic character.

(8.) SCORBUTIC ULCER.—Although scurvy in itself—observes Mr. Busk—cannot be said to be attended with any peculiar form of ulceration, ulcers or sores of any kind already existing from other causes assume, in consequence of the scorbutic taint, a more or less peculiar character, and when thus modified have usually been termed “scorbutic ulcers.” It is the

effusion of a semi-plastic fibrous material—the same as that which causes the spongy swelling of the gums, &c.—on the free surface of sores or ulcers, which gives them the peculiar aspect termed scorbutic. Ulcers of this kind are distinguished by their livid colour, irregular tumid border, around which no trace of cicatrization is evident; whilst the surface of the sore is covered with a spongy, dark-coloured, strongly adherent, fœtid crust, whose removal is attended with free bleeding, and is followed by a rapid reproduction of the same material. This crust, in bad cases, as remarked by Lind, attains to a “monstrous size,” and constitutes what has been appropriately named by sailors “bullock’s liver.”

*Treatment.*—Regarding a scorbutic ulcer as but a manifestation of the blood-disease—scurvy, the appropriate treatment is that which pertains to this disease; and having regard to its apparent dietetic cause, namely, the deprivation of fresh vegetables, remedial measures will consist, chiefly, in their restoration. Hence the well known efficacy, preventive and curative, of potatoes and of lemon or lime-juice.

(9.) SCROFULOUS OR STRUMOUS ULCERS.—Consequent on the ulceration of a scrofulous tubercular swelling, or the opening of a scrofulous abscess, the ulcer is remarkably indolent, yet its characters are unlike those of the ordinary indolent ulcer. Large, pale, flabby granulations, sometimes exuberant, with a gleet discharge, form the surface of the sore; the margin is thin, livid, and undermined, sometimes pretending to heal by encrustation of the discharge. The characters and tendency are those of an ordinary œdematous ulcer; but a scrofulous ulcer is even less disposed to heal *soundly*. A scrofulous cicatrix appears drawn, puckered, and incomplete. Small bridges form across the ulcer, underneath which a probe can be passed readily, in and out, here and there. Nature does but “skin and film the ulcerous spot.” The co-existence of scrofulous swellings and abscess, in other parts, will complete the diagnosis.

Such ulcers are most frequent in the neck, groins, cheeks, scalp; and about the knee, ankle, wrist, and elbow. They are often numerous and clustered.

The immediate cause in operation would appear to be a blood-disease, the nature of which however is unknown. But whatever impairs the nutritive qualities of the blood and its circulation, predisposes to scrofula. Hence deficient or defective food, insufficient ventilation, want of cleanliness and excretion, poor clothing, cold, damp, and even dark localities, with other hygienic conditions of similar import, are the nurseries and nurses of this blood-disease. Individual predisposition, as usual, plays its part; for among a family of children in precisely the same hygienic circumstances, one becomes scrofulous, while the rest remain free.

*Treatment.*—In addition to the removal of any adverse hygienic condition; iron, bark, and cod-liver oil, are calculated to strengthen the circulation and improve nutrition. The digestive organs will also require watchful attention. A stimulating plan of treatment with moderate pressure on the ulcer is appropriate, as for an œdematous ulcer. Thus, nitrate of silver or sulphate of copper, and bandaging, are beneficial as topical appliances; but the more important part of the treatment is constitutional.

The scar of a strumous ulcer is unsightly and may occasion deformity, either by contraction or, more commonly, by over-growth, and the formation of bars raised in radiating lines, or net-works, or tongues of skin. In such cases—observes Mr. Paget—excision of the scar may be

necessary ; but in many instances a great portion of the excess of scar can be removed by repeated slight blistering, and with time nearly the whole will level down.

In a superficial scrofulous ulcer on the hands or feet, excessive growth of the *papilla* at the base or borders of the ulcer, gives a remarkably warty character to the ulcer ; which often remaining after cicatrization, leaves a coarse, nodular, patch of skin, with opaque, thick cuticle. In this particular resembling a papillary epithelial cancer ; the diagnosis of this form of scrofulous ulcer may be determined, by the absence of hardness in the granulations or the base, of a sinuous or upraised border, and of rapidity of progress ; and by the presence of more than one, perhaps many such ulcers.

These warty strumous affections may be cured by repeated applications of iodine-paint.

(10.) **CANCEROUS ULCER.**—Already described in this work, as part of the general history of cancer ; the characters of a cancerous ulcer are here alluded to as compared with those of a lupoid ulcer. The scirrhus ulcer is most distinctive. Beginning in the skin and extending down to deeper textures, or commencing subcutaneously—in a cancerous mass, and extending upwards to and involving the skin ; the ulcer formed in either way, presents an irregular cavity, the surface of which is covered with large, hard granulations, discharging a thin, peculiar smelling ichor ; the edges are elevated, thick, and everted, with much circumferential induration. The neighbouring lymphatic glands are, or become, indurated, and enlarged. The ravages of this ulcer are unlimited.

*Treatment*—see **CANCER**.

(11.) **LUPOID ULCER.**—Commencing as a fissure or soft wart ; the ulcer formed is an excavated hollow, having, commonly, no granulations, the edges sharp and worm-eaten, with no induration around. The lymphatic glands are unaffected. But this ulcer, also, spreads and spares no texture.

As contrasted with a cancerous ulcer, the differential characters, above stated, were early impressed on my mind by two well marked cases which I observed when a student at the University College Hospital. The one, an elderly woman—under the care of Mr. Morton—had a large cancerous ulcer of the leg, which presented the appearances I have described ; the other, a middle aged man, an ostler,—under the care of Mr. Liston—had a large lupoid ulcer of the cheek, with the appearances already noticed,—namely opposite to those of a cancerous ulcer.

*Treatment.*—Various powerful escharotics have been tried with the view of arresting the progress of a lupoid ulcer, and converting it into a healing condition. Chloride of zinc, mixed with flour and forming a paste by deliquescence, was used in Mr. Liston's case. The intense pain, for a time, which followed its application, would now-a-days be subdued by the continued influence of chloroform. Subsequently, poultices, help to bring away the slough. Further extension of the ulcer may be thus arrested, and the cavity evince a tendency at least, to heal. This favourable change took place in the case alluded to, and I have since met with similar instances. Iron, bark, and cod-liver oil, and other means of improving nutrition, seem to have some beneficial influence.

(12.) **SYPHILITIC ULCER.**—Primary, secondary, and tertiary syphilitic ulcers form part of the general pathology of Syphilis.

**MORTIFICATION.**—The transition of ulceration to mortification, as already noticed, will have suggested their mutual relation. As processes,

they differ in degree, but are one in kind. The former may be exaggerated into the latter, and this again may subside into that. Ulceration and mortification are convertible by gradations of the same process, disintegration of structure; the one, molecular, as a liquid discharge; the other *en masse*, presenting accumulations of disintegrated matter. Thus, during ulceration, ever and anon some temporary cause may accelerate the process; a larger portion of tissue undergoes disintegration than can concurrently pass away as discharge; a portion of such matter then appears as slough, instead of having disappeared imperceptibly—molecule after molecule—in ichorous solution. It is as if the “flow” of a tidal stream washed up more material than the returning “ebb” can well recover—the line of coast shows the remaining débris. Even so, the surface of an ulcer may present a rim of slough, and from time to time, another and another, as the margin of the sore recedes and extends.

*Signs.*—*Gangrene*, or the incipient stage of mortification, exhibits certain characteristic appearances. (Fig. 29.) The skin is livid or has a black hue, shading off to a reddish brown around the dying part. Its consistence is changed; becoming soft, with considerable swelling and

FIG. 29.

pitting on pressure, while the cuticle is raised into vesicles containing a yellowish serum or, phlyctenæ—large bladders, full of bloody serum. The part is, in fact, altogether sodden and succulent, from the infiltration of

FIG. 30.

the constituent cellular texture with serum. This condition is the *humid* gangrene of French authors, the *hot* of German writers, and the *acute* of our own school. (Fig. 29.) Or the part may be hard, shrunken, and dry. An

opposite condition, known as *dry, cold, or chronic gangrene*. (Fig. 30.) In either state, the sensibility of the part is diminished, and its temperature reduced. The odour of gangrene is peculiar and pungent; it becomes fœtid with the evolution of gas by decomposition, which, inflating the cellular texture, much increases the swelling; and owing to the admixture of gas and serum, it then has the additional character of crackling under gentle pressure, or of fluctuation like a collection of pus, if the deeper textures be thus distended. The part is irrecoverably dead; mortification having advanced to its second and furthest stage—the condition of *sphacelus*. The textures, in this condition also, may be dry and shrunk; as in senile gangrene which has advanced to sphacelus. In either case the part is insensible and cold.

The anatomical condition of sphacelus is somewhat peculiar. Disintegration of the soft textures still prevails; the bones, indeed, may have undergone but little change, otherwise than appearing dry and bloodless, their periosteum being detached; but the articular cartilages and tendons are dull and slightly softened, while all the softer textures have broken down indiscriminately, with one exception. The bloodvessels alone have escaped destruction. Thus, phlegmonous erysipelas may have laid bare several inches of the femoral artery, by sphacelus of the integuments, and yet that vessel remain intact. The blood also—stagnant and coagulated therein, after death—may remain fluid and circulating during life; or coagulation having taken place the vessel will be impervious, and perhaps to some distance above the seat of sphacelus. Hence the absence of hæmorrhage during amputation in such cases.

CAUSES—*external and internal; and their operation*.—The pathology of ulceration and mortification being essentially the same, their etiology also is the same.

*External agents*: physical—as mechanical violence and injury, heat, cold, electricity; chemical decomposing agents; and vital, as animal poisons introduced into any living texture. Either of these external causes may *immediately* kill the part, or kill, if the tissue be vascular, by *inflammation* supervening and terminating, perhaps speedily, in mortification.

(1.) Violence or injury of any kind may give rise to gangrene, which is thence denominated *traumatic*. It is thus distinguished from gangrene arising from any internal, and commonly constitutional disease—*e.g.*, a blood-condition; and which, as a local manifestation of that disease, is thence denominated *idiopathic* gangrene. This distinction is noticed more particularly, in connexion with contusion and contused wounds.

Of traumatic causes, pressure, or contusion, *directly* applied, severely although momentarily, as by a squeeze, kills the part immediately. A finger caught in the hinge of a door may thus be squeezed to death. Or, pressure, continued, although less severe, excites gangrenous inflammation. In either case, mortification is limited to the part injured. *Indirect* contusion or concussion, as by a fall, may not be more severe, and is certainly a momentary cause; but it produces gangrene or gangrenous inflammation; and the mortification will be more extensive, although still co-extensive only with the part injured.

Pressure or contusion—directly or indirectly—chiefly injures the capillary vessels and smaller arteries; but traumatic gangrene more frequently arises from injury to *larger-sized* blood-vessels. Considerable hæmorrhage takes place, causing gangrene, partly by pressure of the

blood extravasated among the textures, partly or principally by cessation of the supply of blood requisite for nutrition.

Wounds implicating the larger blood-vessels, compound fracture, and dislocation; especially operate in this way. Gangrene is not necessarily limited to the immediate and apparent seat of injury; it may extend—*e.g.*, up a whole limb, but still only as high as the cause in operation. Heat, cold, and electricity, require no further consideration as *causes* of mortification, than that they operate, either by killing outright, or by inducing gangrenous inflammation; cold, however, not seeming to have the power of killing a part at once. A frost-bitten or frozen portion of the body is not irrecoverably dead.

(2.) Chemical decomposing agents, on the other hand, mostly operate by killing immediately—decomposing the living tissues with which they come in contact. Such are caustic alkalies, the concentrated mineral acids, and other escharotics.

(3.) Animal poisons introduced into the body, are generally less immediately killing to the part—*i.e.*, they induce gangrenous inflammation. Bites of venomous serpents represent this class.

*Internal* causes are perversions of the constituent elements of nutrition. Blood of a certain “quality,” suitable to each part for its nourishment, and a certain “quantity” of this blood supplied to and circulated through the part; “an appropriate physical and structural condition of the part itself;” and, some kind of “nervous influence;”—these are the internal conditions, which, when perverted, become internal causes of mortification.

(1.) *Blood-conditions*, by alterations of *quality*, are eminently constitutional causes. Their pathological nature is but little understood; their local manifestations in gangrene, having characteristic appearances, are well known. Some of these blood-conditions were alluded to, in speaking of the varieties of ulcers as depending on constitutional causes. Other such causes more especially give rise to mortification, in various remarkable forms. Thus are produced carbuncle, boil, and the carbuncle of plague; phlegmonous erysipelas, bloody small-pox, malignant scarlatina, glanders, ergotism, scorbutic sloughing, the phagedænic and sloughing buboes of syphilis.

Mortification arising from any blood-disease spreads without limitation, as to its extent.

(2.) The *quantity* of blood supplied to and circulated through any part, depends upon and is regulated by the heart’s mechanism and action, the state of the blood-vascular system—arteries, veins, and capillaries, and the physical condition of the blood itself, chiefly in respect of its spissitude and adhesiveness. These conditions are severally, and collectively, more or less causes of mortification.

Of diseases and malformations of the *heart*, their influence in relation to mortification is impressively illustrated by the following case, which is, I believe, *unique*.

A boy, aged fifteen, came to the Royal Free Hospital, as an out-patient, with bluish-black congestion of the toes of both feet, as high as the instep, and thence shading off in a dusky hue up the legs. The whole surface of the body, was more or less livid, especially the cheeks and lips. The weather was cold, and he had been exposed, with scanty clothing, and had undergone deprivation. But, the circulation was naturally feeble, the bluish, almost cyanotic appearance having been noticed

from birth by those who knew the boy; his expression was anxious and prematurely aged, his manner deliberate and lethargic, and his breathing short and oppressed. After being twenty-four hours in bed, under the cautious administration of stimulants, brandy and ammonia, with hot bottles to the feet, which were wrapped in cotton-wool, the general circulation had somewhat returned; but the congestion of the toes had passed into gangrene, sphacelus speedily ensued, and one or two dropped off. I amputated both feet through the tarsal bones; union in part primary, in part by granulation, took place, forming two capital stumps. Recurring attacks of dyspnœa and lividity proved fatal in a month after operation. Post-mortem examination showed that the immediate cause of death was acute pericarditis and pleurisy. But the heart was much enlarged, its right half extending outwards to the junction of the ribs and costal cartilages.\*

(a) *Arteries* are liable to undergo changes of structure, which are particularly worthy of notice surgically.

*Ossification* or calcareous degeneration of the larger arteries with fibrous thickening of the smaller ones, accompanied, possibly, with some contraction of the vessels; lead to coagulation of the blood in tubes which have thus become too rigid for the transmission of that fluid, in quantity adequate to meet varying demands. This condition represents the changes of structure concerned in producing "senile" gangrene,—a dry form of mortification, commonly affecting the foot, when the arteries of the leg have undergone these changes. Some slight injury, followed by low inflammation, is usually the immediate or exciting cause in such cases. Traumatic gangrenous inflammation, is in fact, engrafted on the state of the arteries,—as a predisposing condition. Mortification, commencing generally in a part most distant from the heart, as the ball of the great toe, and thence spreading upwards, gradually assumes the appearance of a black slipper on the foot.

*Arteritis*,—inflammation of an artery—is a far less frequent cause; it acts in a similar manner, and may induce gangrene of the same character, or more dry and horny.

*Fibrinous coagulum*, not formed in the artery where it is found impacted, but washed from the left ventricle of the heart and carried thence by the current of blood to that vessel; is another cause of gangrene, perhaps merely an occasional one, but the pathology of this condition has only recently been investigated. An artery thus impacted with a clot, is known as "embolism."

*Rupture* of the internal and middle coats of a large artery, by violence, may induce coagulation; the loose portion folding inward across the stream of blood. Mortification is liable to supervene.

*Aneurism* is another cause; partly by interrupting the free flow of arterial blood through the aneurismal artery, and partly, by pressure on adjacent veins, obstructing the return of venous blood. Popliteal aneurism will thus induce gangrene, which soon passes into sphacelus.

*Wound* of a main artery acts in two ways. A punctured wound may be an immediate cause, by loss of blood. A contusion or bruise may lead to sloughing of the vessel, after some days have elapsed; this being attended with hæmorrhage and false aneurism, followed by mortification. Laceration of the vessel may, in like manner, have the same issue. In

\* Examination not concluded on going to press.

either case, the integuments may have escaped injury. Simple fracture, and perhaps, simple dislocations, will thus lead to mortification, occasionally. Compound fracture and dislocation, far more frequently.

It is highly important to observe the *partial extent* to which gangrene is liable to spread, in connexion with all these vascular lesions, as contrasted with gangrene arising from any constitutional cause. Unlimited in that case, it is here limited in extent to the *source* of gangrene, and probably restricted to less than that extent, by the enlargement of branches coming from the artery above the seat of injury, which supply a collateral and compensatory circulation of blood. Thus limited is the gangrene arising from the ossification of arteries or senile gangrene; from arteritis; from embolism; from partial rupture of an artery; from aneurism; and from wounds of an artery, whether punctured, contused, or lacerated. But, then, the limitation connected with *some* of these causes,—the point to which gangrene may extend—can scarcely be determined during life. This is the practical ground of distinction between senile gangrene, arising from *ossification* of the arterial vessels, and *traumatic* gangrene; and in favour of the latter, the limitation of which can be more definitely *predicated*. Failing this fore-knowledge, the Surgeon must wait the “line of demarcation,” drawn by nature.

(b) *Veins* are less liable to become causes of mortification; obstruction to the return of venous blood from any part of the body, having a less important relation in this respect, than obstruction to the supply of arterial blood.

*Phlebitis* induces coagulation of blood within the vein or veins inflamed, and this obstruction is attended with œdematous swelling of the limb or part below. The swelling becoming tense and persistent, is a condition bordering on gangrene. *Phlegmasia dolens*, in which the iliac and femoral veins, the main venous trunks of the limb are inflamed; thus perils the leg below.

*Fibrous obliteration* of a venous trunk is another such cause, once in a way, of tense anasarca.

*Phleboliths* or vein-stones, not unfrequently formed within various veins, more particularly the iliac, have a similar tendency.

*Aneurismal varix* and *varicose aneurism*, resulting from a communication between an artery and a companion vein, as from unskilful venesection at the bend of the elbow; is attended with venous engorgement, persistent, and increasing, and œdematous swelling of the limb below, threatening gangrene.

*Prolonged pressure* on a large vein, itself in a healthy state, is an extraneous cause of obstruction to the return of venous blood. Tumours, and tight bandaging, may thus, indirectly, have this effect in relation to mortification.

The *limitation* of gangrene is no less characteristic of that which arises from obstruction in the course of a large vein, than from obstruction of a main artery; the gangrene, in either case, extending possibly up to, and probably within, that situation.

Thus *both* classes of causes, those pertaining to the arteries and those pertaining to the veins, concur; and differ from any constitutional cause, in relation to gangrene.

The limitation also dependent on *some* venous causes, like that dependent on certain arterial causes, can scarcely be *foreseen*. *Diseased* conditions of veins are more often perplexing in this respect, as compared

with any tendency to gangrene of *traumatic* origin from injury to a large vein.

(c) *Capillaries*.—*Compression* of these vessels is followed by gangrene of the part, if thereby deprived of a due supply of blood.

*Inflammation*, therefore, with lymph-production, and compression of the capillary vessels, reacts destructively upon the textures. Moreover, inflammatory products, for the most part, are inherently short-lived. And especially during suppuration, the surrounding textures are dying, disintegrating, and being absorbed to make room for the new product—pus; destruction and production here usually keeping pace. Hence the formation of *abscess* necessarily pre-supposes the death and absorption of the textures around; and co-extensively with the formation of pus, which now occupies their place. Sometimes, they die faster than absorption can remove them, and then their mortification—as sloughing of the soft textures or a sequestrum of dead bone—becomes plainly visible.

Certain conditions *predispose* to gangrenous inflammation. Blood-poisons are constitutional causes of this kind; as in the production of carbuncle and boil, phlegmonous erysipelas, and the other forms of gangrenous inflammation, already mentioned in connexion with the constitutional causes of mortification. Intensity of inflammation has a similar tendency. And lastly, the vascularity of the texture affected; a comparatively avascular tissue readily becoming gangrenous, and especially if looseness of texture permit the accumulation of serum; as the cellular tissue, in erysipelas, and any texture under the pressure of effusion beneath an unyielding investment, as the tendinous expansion of the occipito-frontalis muscle.

(3) *Physical and structural* conditions of the part in relation to mortification generally.

Of physical properties; an *unyielding fascia* or aponeurosis—*e.g.*, the fascia lata, predisposes subjacent textures to gangrene, by pressure in the event of any effusion of blood or serum therein. *Looseness* of texture also predisposes to this issue, by favouring an interstitial accumulation of blood or serum. Traumatic gangrene is determined, partly by these physical conditions, impeding the nutrition of the part; although mainly, by the insufficient circulation of blood, depriving it of adequate nourishment, and by the damage which the textures have directly, or indirectly, sustained by violence. Structural conditions predispose to mortification; the proportion of blood-vessels having this relation. Both extremes meet—comparatively *avascular* textures have a tendency to gangrene; *e.g.*, the liability of cellular texture to slough, from any cause. Highly *vascular* textures also have a similar tendency, apparently by favouring the intensity of inflammation and effusion; *e.g.*, the skin as compared with fibrous or tendinous textures, which often resist sloughing long after the integument has disappeared in consequence of an extensive burn.

Predisposition to gangrene from textural conditions, is most conspicuous when they are *co-operative* causes. Cellular texture for example, being comparatively avascular, as well as liable by its looseness to become the seat of interstitial effusions, most readily sloughs.

*Causes of Ulceration*.—By some variation in the *degree* of any cause of Mortification, this process of mass-disintegration subsides into that of molecular disintegration. Ulceration is mortification by small instalments. Consequently, similar conditions of texture *predispose* thereto. Thus, with regard to vascularity; the less vascular textures are prone to

ulcerate, as well as mortify,—*e.g.*, cellular-texture, and cicatrix-tissue; in this respect agreeing with the liability of the highly vascular skin, and mucous membrane, to inflammation and thence to ulceration.

The comparative liability of different textures to ulceration and mortification, is well shown in the natural process by which a dead limb is gradually separated from the living tissues; they detaching themselves from the dead. All, excepting the cellular texture and tendons, are severed by ulceration forming a fissure, which is progressively incisive down to and through the bone. The dead skin, vessels, muscular tissue, and bone are severally detached evenly, by ulceration; but the cellular texture and tendons die for some distance upwards within the stump, and are detached irregularly, by sloughing.

(4) *Nervous influence*, of some kind, plays an important part in mortification and ulceration. For example; injury to the spine has been followed within twenty-four hours by mortification of the ankle; and the tendency to ulceration in such a case, or of the cornea in connexion with facial paralysis, is equally remarkable.

Considering the whole etiology of mortification and ulceration practically, the most important general fact is the *co-operation*, usually, of two or more causes, in either mode of death; whereby it is difficult to determine the share due to each internal condition, more especially in conjunction with the operation of external circumstances, such as moisture, temperature, etc.

*The Fever of Mortification*.—Coincident with mortification, as the local disorganization, the constitutional disorder at once commences. Its phenomena or symptoms, are generally more insidious, but not unlike those of Pyæmia, though differing in degree. A wild apprehensive look, with great restlessness, are conspicuous; the features and manner at length become somewhat composed, and the face assumes a pallid hue. In some cases, the tunica conjunctivæ, and the skin over the whole body, acquire a peculiar yellow colour. Utter prostration of mind and muscular power gradually supervenes, and a quivering subsultus tendinum steals over the patient. The pulse is now very feeble, rapid, and irregular, feeling like a fine rough wire drawn under the finger, and perhaps scarcely to be distinguished from the vibrating *subsultus* of the adjoining tendons. The secretions are soon perverted. The skin, at first hot and dry, is afterwards bathed with a cold, clammy sweat. The urine, fœtid and scanty, may be suppressed. A brown, rough, dry tongue with black sordes encrusting the lips, are accompanied with nausea and a putrid diarrhœa. The powers of organic and of animal life failing, involuntary excito-motions prevail; spasms and convulsions shake the moribund body, while coma ends in death.

Or, the mortification ceases to spread. The reddish brown tint of the skin bordering the dead part, and which has hitherto spread in advance, gets brighter and more circumscribed. A white raised line—the “line of demarcation”—forms in the living skin immediately adjoining the dead; it melts into a groove by ulceration, which extending deeper and deeper, as a fissure, successively passes through tissue after tissue, and at length converging, thus completely detaches the whole of the dead part. Pending this course of severation from the living organism, adhesive inflammation precedes the line of ulceration, and, corresponding to it in length and depth, seals the blood-vessels; thus effectually excluding any further communication with the dead tissues and preventing their absorp-

tion for the time to come. The typhoid fever immediately begins to subside, and ultimately ceases. In exchange, some degree of "inflammatory fever" accompanies the concurrent process of ulcerative separation and reparative adhesion.

Such is a descriptive outline of the origin, course, and termination, fatal or favourable, of the constitutional disorder proceeding from mortification. Arising with spreading gangrene, it ceases when the dead part is detached from the living body. Respecting the obvious dependence of this fever on mortification; these two general facts, taken conjointly, seem to warrant the conclusion, that absorption of the dead tissues as the connecting link is the immediate cause of the fever. The presence of gas, as decomposition supervenes on sphacelus, is probably a co-operative cause, subsequently, by its direct influence on the nervous system. Absorption of dead matter primarily, nervous sympathy secondarily, and ultimately both together, induce and maintain the typhoid fever which proceeds from mortification.

#### TREATMENT OF MORTIFICATION.

Taking a comprehensive retrospect of the pathology and etiology of (ulceration and) mortification, the Indications of Treatment are four:—

(1) To remove the cause or causes, in operation, and thus arrest the progress of death.

(2) To remove the dead part—*e.g.*, a slough, a sequestrum, a limb; and the proper time for such surgical interference.

(3) To solicit the natural separation of the dead part, with reparative closure of the blood-vessels, simultaneously and co-extensively; and the reparative process of granulation and cicatrization, subsequently.

(4) To control the constitutional disorder, consequent on mortification.

(1) The causes of Mortification are, as we have seen, external and internal.

Of *External* causes; some only are persistent in their operation, and therefore practically important in that respect. Mechanical violence, heat, cold, electricity, as lightning, and chemical decomposing agents; are external causes, the operation of which is all but momentary. Animal poisons introduced into any part of the body, are persistent causes, so long, at least, as any such poisonous matter continues operative. Hence the importance of their early removal. This may be accomplished in various ways.

The application of a cupping-glass is calculated to withdraw the poison, and without sacrificing the part. Free excision of the part itself, may remove the poison, but with a proportionate mutilation. Neutralization of the poison by caustics, or the actual cautery, with destruction of more or less of the textures, *in situ*; is a resource of an intermediate character. A bandage applied with some tightness above the part affected, in the case of a limb, may prevent poisonous matter from entering the general circulation.

Of these four appliances, cupping is the most practicable and effectual.

Of *Internal* causes; some only are removable by any known remedial measures.

*Blood-conditions*, as pertaining to some altered *quality* of the blood in circulation, are thus, for the most part, beyond control. Such are the blood-diseases of carbuncle and boil, erysipelas, small-pox, malignant scarlatina, glanders, ergotism, scurvy, and constitutional syphilis; the two last more especially inducing ulceration.

Conditions pertaining to a deficient *quantity* of blood as causes of mortification, are more amenable to treatment.

(a) Arteries are liable to six such causative conditions, three of which may be effectually overcome—Arteritis, Aneurism, and Wound of a main artery. The first-named disease should be treated according to the rules laid down for inflammation in general; the second and third conditions are fully considered with regard to treatment, under their respective headings.

(b) Veins are liable to five analogous causative conditions; three of which are remediable—Phlebitis, Aneurismal Varix and Varicose Aneurism, and prolonged Pressure on a main vein, as by a tumour or tight bandaging. The treatment of these conditions will be found in their proper places.

(c) Capillary vessels in relation to mortification, are commonly associated with the pathology of Inflammation. Defective capillary circulation, as connected with a comparatively avascular condition of structure, is another internal cause; and intensity of inflammatory hyperæmia and effusion, as dependent on a highly vascular condition, is a third such cause. The one suggests stimulating embrocations, friction, and other similar appliances, to promote the deficient circulation—*e.g.*, in the treatment of bed-sores resulting from pressure which reduces the skin to a virtually avascular condition. The other condition suggests local depletion, and other similar measures, as for inflammation.

Ulceration, resulting from causes precisely analogous to those of Mortification, will require similar measures for their removal. Thus, for example, chilblains, occurring as they do in persons of weak circulation, are prone to ulcerate, and are best treated by spirit lotions and other stimulating applications.

Lastly, defective *nervous influence*, of some kind, has an important causative relation to Mortification and Ulceration; but the removal of this internal cause—the restoration of such influence—may be very difficult. If the occasion of defective nervous influence be local and mechanical, as pressure from a tumour on a nerve, above the seat of sloughing; its removal will be curative. But in some such cases, the source of pressure may not be accessible; and in others, persistent or recurring, thus frustrating the treatment. [P. p. 566.] In cases not referable to any mechanical cause, strychnine administered in small doses,—the sixteenth or twelfth of a grain, and continued until some slight tetanic twitchings of the muscles ensue, may have some efficacy in restoring nervous influence; and galvanism in like manner.

(2) Removal of the dead part by operation, and the proper time for such surgical interference.

As the *immediate* cause of the constitutional disorder, removal of any mortified part,—a slough, sequestrum, or a limb, is an indication of treatment obviously necessary. But the earliest opportunity for fulfilling this indication, with due regard to the non-recurrence of gangrene in the part adjoining, may be a question for the Surgeon's consideration.

The removal of a loose slough of soft textures or a sequestrum of

bone, cannot admit of any such doubt; for there and then, mortification has become defined.

*Amputation* of any part, as a limb, is a question respecting the *spreading* of gangrene, and the probability of its *recurrence* in the stump.

The consideration which *partly* determines this question is, the constitutional or the local origin of the gangrene. In the former case, spreading *without limitation*, as to its extent, amputation must be postponed *until* the "line of demarcation" has formed; in the latter, limited in its extent to the *source* of gangrene, and probably restricted to within that boundary,—by the establishment of a collateral circulation, from above to below; amputation may be performed *prior* to the formation of the line of demarcation.

But in *certain* of these naturally limited gangrenes, the limitation cannot be *foretold*, simply because the exact situation of the causative condition cannot be diagnosed. Of arterial conditions; such are ossification of a main artery or arteries, leading to senile gangrene; arteritis, indefinite in a lesser degree, as to its extent; embolism; and partial rupture of an artery without any external wound. Of venous conditions; such also are fibrous obliteration of a large vein; phleboliths or vein-stones impacted; and phlebitis, indefinite as to its extent. Hence, in all these cases, arterial and venous—the treatment appropriate for the particular causative condition having failed—amputation must be deferred until *such time* as nature has indicated by the formation of the line of demarcation, that limitation which cannot be foreseen. The venous conditions referred to, seldom, if ever, necessitate amputation.

On the other hand, the line of demarcation can be foretold, in other cases of *definitely* local origin. Such are aneurisms—spontaneous and traumatic, and wounds of a main artery; aneurismal varix, and varicose aneurism; and any occasion of prolonged pressure on a large vein. Hence, in all *these* cases,—arterial or venous,—the treatment appropriate for the particular causative condition having failed—amputation may be resorted to before the formation of the line of demarcation has indicated the actual extent to which the gangrene will spread. Generally speaking, the rule for amputation may be thus stated, in all cases of local origin; *idiopathic* gangrene, however caused, suggests the postponement of amputation *until* the limitation of gangrene is declared by Nature; whereas, *traumatic* gangrene, however caused, suggests amputation more immediately; the anticipation of Nature by Surgical Art, then being justifiable. Two exceptions are urged by Erichsen—namely, gangrene from frost-bite, and that from severe burns. In these injuries, he considers it better to wait for the formation of the line of separation, and then to fashion the stump through or just above it, as the circumstances of the case require.

In *Spreading* traumatic gangrene, the question of amputation should be determined rather by the consideration that a constitutional cause is in operation. Postponement of amputation, therefore, pending the formation of the natural line of demarcation, is the rule of treatment.

(3) Solicitation of the natural separation of the dead part, with reparative closure of the blood-vessels, simultaneously and co-extensively, and the reparative process of granulation and cicatrization, subsequently.

*Constitutional* gangrene, and gangrene arising from *local* conditions the exact situation of which cannot be diagnosed; may have compelled the postponement of amputation, pending the natural limitation of gan-

grene; but Surgical Art should solicit this limitation, and thus also, if possible restrict the extent to which the gangrene might otherwise have spread. By maintaining the *temperature* of the part, not yet mortified, the local circulation may become diffused sufficiently to sustain its vitality; whereby the line of demarcation between the living and the dead portions will be declared. Hence, the preventive value of cotton-wool, with which material the limb should be deeply enveloped. This padding need not be reapplied for some days, the gangrenous part being covered with lint soaked in a chlorinated, carbolic, or other antiseptic lotion.

In *senile gangrene*, the line of demarcation having formed, and separation of the dead part, slowly taking place; reparative closure of the blood-vessels will be promoted by a light poultice or epithem of moist spongopiline, to encourage adhesive inflammation. When the soft textures are thus safely detached, the bone may be sawn through, and the otherwise natural amputation completed by this amount of surgical interference.

Granulation and cicatrization supervene as in the healing of a healthy ulcer, although perhaps more slowly than usual. Simple water dressing or some gently stimulating lotion, will therefore generally prove sufficient in the way of topical treatment. Balsam of Peru, pure or diluted, with an equal part of yolk of egg, is highly recommended as an application in these cases. Remembering the persistent cause of gangrene—namely, ossification of the arteries; exposure to cold must ever be avoided, and the circulation in the legs cherished by the patient wearing thick woollen socks, flannel drawers, and other such warm clothing.

(4) *Constitutional Treatment*.—Prior to closure of the vessels, the constitutional disorder consequent on gangrene—the *typhoidal* fever, requires supporting measures; an easily assimilated diet, comprising proportionately more animal food, malt liquor, and alcoholic stimulants, will prove most beneficial. Of medicinal stimulants and tonics; the sesquicarbonate of ammonia and chlorate of potash, with cinchona bark or cascarilla, form a combination, which is, I think, more lauded in the books, than suggested by pathology or sanctioned by experience. Opium is, generally, a remedy of great value, apparently by subduing the nervous excitement and promoting the capillary circulation, thus aiding the process of separation. It should be administered in small but repeated doses, to the amount of from two to four grains in the twenty-four hours, and increased as the system is brought under its influence; but opium is contra-indicated or must be discontinued, whenever it disturbs the digestive organs or occasions headache.

*Inflammatory* fever, in some degree, accompanies occlusion of the vessels during the separation of the gangrenous part; opium may therefore still be continued to suppress nervous excitement and the heart's action, while it sustains adhesive inflammation. Any topical measures to regulate the inflammation are unnecessary, or would be absolutely provocative of gangrene unless applied with the most tentative caution.

This due consideration and balance of constitutional and local treatment, with watchful supervision of the remedial agents employed, constitutes the scientific practice of medical and surgical art as responsive to the ever-changing conditions of pathology—the body in disease.

## DISEASES OF THE BLOOD.

## CHAPTER V.

## SCROFULA.

SCROFULA is a constitutional disease of "blood-origin" because possessing the family features of this class of diseases. In tracing these family features throughout the various local manifestations of scrofula, I shall not include those of an allied blood-disease—Tuberculosis; for these diseases do not appear to be identical, as some pathologists have maintained, and even still allege. I endorse the view held by Mr. Paget, that *this* is their relation—"the scrofulous constitution implies a peculiar liability to the tuberculous diseases, and that they often co-exist." But "their differences are evident, in that many instances of scrofula (in the ordinary meaning of the word) exist with intense and long-continued disease, but without tuberculous deposit; that as many instances of tuberculous disease may be found without any of the non-tuberculous affections of scrofula; that, as Mr. Simon has proved, while diseases of 'defective power,' may be experimentally produced in animals by insufficient nutriment and other debilitating influences, tuberculous diseases are hardly artificially producible; and that nearly all other diseases may co-exist with the scrofulous, but some are nearly incompatible with the tuberculous."\*

*General Symptoms.*—Scrofula—thus distinguished from tuberculosis—exhibits itself locally by "mal-nutrition and chronic inflammation." This inflammation is scarcely expressed by pain or heat, or redness, but rather by swelling, more or less considerable and doughy, slowly enlarging, and tending to suppuration; yet scrofulous suppuration is unwilling, so to speak, and the pus a mixture of curd and serum. Should a scrofulous abscess point, the skin thins, but gradually, and assumes a purplish tint; an irregular rent follows after some time, and the flaky matter rolls out. Perhaps this aperture gets blocked up and imperfectly closed; the matter reaccumulating, again to be discharged, and so on from time to time. Or the aperture may remain free, with puffy everted edges of a purplish colour, and the discharge continue—now thick, now thin.

The *scrofulous ulcer*, which eventually results is equally indolent. It persists, with a thin, livid, undermined margin, large, pale, flabby granulations and a gleet discharge; although sometimes pretending to heal, by this discharge crusting over its surface. Should cicatrization ensue, the scrofulous cicatrix appears drawn, puckered, and incomplete. Small bridges form across the ulcer, underneath which a probe can be passed readily, in and out, here and there. Nature does but "skin and film the ulcerous spot."

*Special Forms.*—Scrofula is essentially a "pervading" disease. It blossoms and bears fruit chiefly in the absorbent glands, in the skin and cellular texture, mucous membranes, bones and joints, eyes, salivary

\* Surg. Pathology, 1853, vol. ii.

glands, tonsils, ears, breasts, and in the testicles. Then, again, in some cases, various parts are simultaneously affected, in others consecutively; the scrofulous affection "migrating" from one texture or part to another texture or part. But their order of priority cannot be stated with accuracy. In some textures, the scrofulous affection is more *pronounced* than in others.

*Absorbent glands*, so called, appear to invite the deposit of scrofulous matter. At first soft and fleshy, these glands enlarge and harden; "portions of each gland are observed to have altogether lost their flesh colour, and acquired a degree of transparency, and a texture approaching to that of cartilage."\* At length, a soft, white, or yellowish, curd-like substance is deposited. Glandular tumours, thus formed about the neck and groin, sometimes attain an enormous size; in the latter situation, being perhaps half as large as the head of a new-born child. An enlarged scrofulous gland is not necessarily impervious—at least, mercury can be injected in many instances.† Scrofulous glands are remarkably indolent, but eventually they soften and discharge the characteristic pus, —flaky and ichorous, perhaps cretaceous matter; or they remain as soft and spongy tumours, beneath a thin, silky cuticle, which frequently breaks and oozes; or they waste, and are at length represented only by "a few bands of condensed cellular tissue attached to the cicatrized integument."‡

Absorbent *vessels* are said to be rarely the receptacles of scrofulous matter, but there are such instances on record.

Chronic enlargement with suppuration of the lymphatic glands is one of the earliest characteristic manifestations of scrofula. In childhood, therefore, these glands may be found as just described, in various stages of scrofulous inflammation and suppuration. Yet this is a rare event in children under two years of age. Thomson witnessed it earlier than this, and Cullen mentions a case in which the disease broke out at the very early period of three months. Taking the other extreme, Thomson found the mesenteric glands affected with scrofulous inflammation in persons of *very* advanced age.

In various parts, also, of the body, the lymphatic glands may become scrofulous. Those in the neck—*glandulæ concatenatæ*—are perhaps most frequently affected; and, according to Thomson's experience, scrofulous enlargement, &c., of these glands is more commonly symptomatic of irritation in neighbouring parts than an idiopathic condition,—provided, in either case, the scrofulous diathesis be present. This enlargement of the cervical glands is apt to arise from slight and transitory injuries and affections of the hairy scalp, ears, eyes, nose, and more particularly from slight and temporary affections of the teeth, gums, and other parts within the mouth. Decay of the first teeth is often the immediate cause of scrofulous glandular swellings in the neck, but their eruption, seldom or never.§ The axillary and crural glands are less frequently affected than those of the neck; and Thomson believes that their enlargement also is symptomatic, in this case, by absorption of scrofulous matter from parts more or less remote. This authority was acquainted with but few instances of idiopathic scrofulous swellings of the glands in the groin or armpit. The mesenteric glands are very liable to undergo scrofulous inflammation,

\* Med.-Chir. Trans. Edin., vol. i. p. 683. (Abercrombie.)

† Cyclop. Practical Medicine, 1834, vol. iii. p. 705.

‡ Ibid.

§ Lectures on Inflammation, p. 157.

constituting that formidable disease, *tabes mesenterica*, by arresting the absorption and passage of chyle through these glands, and thus inevitably depriving the whole body of its nutriment. A tumid abdomen, with progressive emaciation, begets suspicion of this disease; while detection of the mesenteric mass, by palpation and percussion, will go far towards confirming our diagnosis. Besides, however, the physical signs and their interpretation, which Pathology supplies, there are, as regards all diseases, with few exceptions, other circumstances whose evidence should be weighed. We look for the concurrence of some other expressions of the scrofulous diathesis. Age, also, should be taken into account; but, in this respect, Thomson found the mesenteric glands affected in children two years old, in persons between twenty and thirty, and in those who had passed their sixtieth year.

The *cellular texture* is peculiarly liable to exhibit scrofulous swellings, bordering on suppuration or actual collections of matter.

In the subcutaneous cellular tissue, small *nodules* are apt to form closely resembling scrofulous glands in appearance. Of this kind are the swellings described by Thomson as being "soft and puffy," and having little or no disposition to suppurate. "They often appear very suddenly; and from the absence of pain and discoloration, they may exist a long time without being perceived. They are usually of an oval figure, and seem to be produced by the effusion of a fluid into the interstices of the cellular texture; they are very variable in their size, being one day more prominent and tense, and the next more flaccid." Subcutaneous *abscesses* may form, and are usually numerous. When an absorbent gland suppurates and bursts, a fistulous sore is the result; but abscess in the subcutaneous cellular texture commonly terminates in an open scrofulous ulcer.

In the *sheaths of muscles*, large chronic abscesses sometimes gather insidiously, containing the pus which characterizes scrofulous suppuration.

The *skin* is more than liable—it is prone—to scrofulous eruptions and ulceration. Its wrinkled seams and puckered scars are familiar to common observation. And these vestiges are not unfrequently "symmetrically" disposed on either side of the body. Indeed, this symmetrical distribution is more common in scrofulous affections of the skin, or at least, is more apparent in that texture, than in those of other textures. An instance of remarkably symmetrical scrofulous scars on the neck and fore part of the chest, occurred in a patient of mine at the Royal Free Hospital. In the middle line, a vertical scar extended downwards to the sterno-clavicular articulation, terminating in a kind of root, and upwards to the os hyoides. From thence a branch scar passed upwards and backwards to the angle of the jaw, on either side; and from this again, on either side, another seam extended upwards to the mastoid process, and downwards on the sterno-mastoid muscle. Either axilla was the seat of an horizontal seam, which discharged a small quantity of scrofulous matter. According to the special experience of Erasmus Wilson,\* cutaneous scrofula is presented in two conditions—that of *tubercles*, and that of *ulcers*. Scrofulous tubercles are small, purplish or livid, indolent tumours. They soften internally and discharge an imperfect pus, remain open or fistulous for a long time, and on disappearing, frequently leave

\* Diseases of the Skin, 1857.

hard knots in the skin. They appear on the neck and face, and near ulcers resulting from inflammation of the absorbent glands. When such tubercles have partially discharged their contents, a crust of inspissated matter forms, which being rubbed off occasionally, exhibits an open sore, with an ichorous discharge, and no disposition to heal. Eventually an ugly cicatrix or scar marks the site of these sores. Usually but one scrofulous tubercle arises; sometimes a group of three or four close together, which may have a circular arrangement, enclosing an area of thin, shining, livid or purplish skin. Rings of this kind occur chiefly on the back of the hands and feet. They are very intractable.

The characters of the scrofulous ulcer need not be repeated. An irregular, livid, and puckered scar is its remnant. Such cicatrices are seen mostly in the neck, near enlarged glands, and in the neighbourhood of joints.

Inflammation of the *matrix* of one or other of the *nails* is not uncommon, more particularly in young persons having the scrofulous diathesis. Scrofulo-derma ungueale, so named, begins by inflammation of the skin immediately around the edges of the nail about to be affected; then follows considerable swelling, with vivid redness of the end of the finger, extending even to the bone, and presenting the appearance of a clubbed finger. The nail is shed, disclosing an angry raw surface, upon which, from time to time, there reappears a rugged, ill-formed and imperfect nail. Fungous granulations and unhealthy pus continue for perhaps many months.

Other *cutaneous* manifestations of scrofula are noticed by some writers. Porrigio favosa, larvalis, and furfurans; eczema impetiginodes and rubrum, in their chronic forms; and that variety of lupus which appears as small, red, button-like, indolent tubercles, chiefly on the lips and nose, occasionally on the genitals. These tubercles excoriate and run into eroding ulcers, with pale, shining, spongy granulations and encrusted margins; or perhaps this work of destruction is concealed by a thick incrustation, which every now and then drops off, exposing its subjacent ravages.

The *osseous system* and the *joints* seem to invite scrofulous inflammation—in this respect contrasting with the indisposition evinced by these structures towards the syphilitic poison, unless reinforced by mercury. The bones and joints, then, are conspicuous in the history of scrofulous manifestations. And both may be coupled together, because it is *near* to joints that the bones are commonly affected. In the extremities of long bones, or in the bones of the carpus and tarsus, their cancellated portion, chiefly, undergoes a series of structural changes, which, with the symptoms, or rather, signs by which they are denoted, will be traced consecutively in describing Diseases of the Bones. I allude to scrofulous caries. Sometimes this species of mal-nutrition runs its course within the *shaft* of a long bone, but generally speaking, as I have said, in the neighbourhood of joints. The latter are secondarily invaded, caries so placed then being denominated “scrofulous disease of the joints.” An inflammation of the synovial membrane, known as “scrofulous synovitis,” was formerly regarded as a primary and distinct disease. More than probably, however, it arises by extension of the destructive process from the cancellated bone.

In the career of scrofula, *mucous membranes* are not exempt from harm, particularly if its blood-associate, tuberculosis, be considered an ally. The eyes, ears, nose, upper lip, tongue, tonsils, salivary glands, and

larynx, severally exhibit scrofulous inflammation; yet this is not altogether limited to the mucous membrane in connexion with these parts.

Scrofulous ophthalmia is a variety of conjunctivitis, characterized by great intolerance of light; so that the child (for this affection occurs mostly in young subjects) seeks a dark room, or buries its head in the bed-clothes, and screws its brows together with screaming agony on any attempt being made to examine the eyeball. From habitually endeavouring to exclude the light, the corrugator and orbicularis muscles become hypertrophied, eventually giving a remarkable heaviness of expression. When the eyelids are separated, a copious flow of tears trickles down the cheek, excoriating the face. The eyeball is now involuntarily upturned to avoid the light, a patchy redness is observable on the conjunctiva, and vesicles or pustules are seen here and there at the margin or on the surface of the cornea. These pustules burst and expose small ulcers. Frequently an interstitial deposit overshadows the whole cornea, which thus becomes thickened and opaque (pannus), projecting also, so that the eyelids cannot be closed. This is one destructive sequel, and should ulceration of the cornea not terminate comparatively favourably—in specks of opacity, perforation of the anterior chamber is inevitable, the aqueous humour is discharged with prolapsus of the iris, and the eye collapses.

Fretting ulceration of the Meibomian glands, attacking the margin more especially of the eyelids, and known as ophthalmia tarsi, is a frequent concomitant of scrofulous ophthalmia; or this diseased condition extends to the iris, giving rise to scrofulous iritis. But there is nothing characteristic about this variety of iritis, taken *per se*; and indeed it is only as one of a *series* of local manifestations that we venture to designate it “scrofulous” iritis, and refer the whole series to one and the same constitutional cause in operation.

The organs of hearing do not escape. Chronic suppuration perforates the tympanum; the ossicula crumble, loosen, and are washed out by the discharge.

The nose assuredly enjoys no immunity. Habitual swelling, ulceration, and fœtid discharge from the pituitary membrane—ozæna—may or may not be accompanied with caries and discharge of portions of the spongy bones.

The upper lip is commonly tumid, protuberant, and chapped. Fissures also and ulcerated spots are seen on the tongue. Nodules, moreover, superficially imbedded in the substance of this organ are said to arise in most instances, and to present the following characters. They vary in size from a small shot to that of a horsebean; are painless, unless subjected to firm pressure, which occasions a pricking sensation. The superimposed mucous membrane reddens, soon breaks in the centre, and forms an ulcer, which spreads and destroys by sloughing erosion; accompanied with much pain, profuse salivation, furred tongue, and fœtid breath. If cicatrization ensue, hardness still remains; fresh nodules also form in other parts of the tongue.\*

Chronic and considerable enlargement of the tonsils, with perhaps indolent ulceration, is another outbreak of the scrofulous diathesis; so likewise is swelling of the sub-lingual, sub-maxillary, and occasionally the parotid salivary glands; but these affections alike owe their significance to the invariable co-existence of other local diseases of more unequivocally scrofulous origin.

\* Cyclop. Practical Medicine, 1834, vol. iii., art. Scrofula.

This remark holds good of another inflammation of mucous membrane, and the last which I shall notice in connexion with scrofula. Chronic laryngitis may be due to this constitutional cause. The vocal cords become thickened; the voice therefore is hoarse or squeaking, and the breathing embarrassed; a tickling cough from time to time ejects a slimy, not frothy, expectoration, streaked with blood perhaps; or the sputa are muco-purulent. In either case the breathing is relieved by this expectoration; but eventually ulceration of the rima glottidis renders its closure imperfect, the act of coughing incomplete, and expectoration therefore difficult; respiration is proportionately more embarrassed. Should ulceration of the epiglottis supervene, there will be a corresponding difficulty of deglutition. I need not enlarge this description; sufficient for my purpose to identify chronic laryngitis, while the invariable co-existence of other local affections of more exclusively scrofulous origin associates this disease with that series of local manifestations which proceed from the scrofulous blood-crisis.

In like manner I have to notice a certain *mammary tumour*, first described by Sir A. Cooper.\* “In young women,” says this author, “who have enlargement of the cervical glands, I have sometimes, though rarely, seen tumours of a scrofulous nature form in their bosoms, confined in most cases to a single tumour in one breast; but in one case two existed in one breast, and one in the other. They are entirely unattended with pain, are distinctly circumscribed, are very smooth on their surfaces, and scarcely tender to pressure. They are very indolent, but vary with the state of the constitution, diminishing as it improves, and increasing as the general health is deteriorating. They can only be distinguished from simple chronic inflammation of the breast, by the absence of tenderness, and by the existence of other diseases of a similar kind in the absorbent glands of other parts of the body. They produce no dangerous effects, and do not degenerate into malignancy.”

Lastly, a peculiar enlargement of the testicle, or rather, of the *epididymis*, is worthy of special notice among the local manifestations of scrofula; and it particularly exhibits the usual characters of stealthiness and slow development. A small nodule, consisting of yellow friable matter deposited within the tubules or ducts, appears generally at one end of the epididymis; little pain or tenderness attends this structural change, and it may progress without complaint. Another and another such nodule forms on the surface of the testis, but generally connected with the epididymis, which becomes beset with three or four small tumours. Thus the testicle itself feels enlarged and irregular at an early stage of this disease.

It has been stated† that scrofulous matter is also deposited within the body of the testis, in the form of pearly or greyish bodies, of the shape and size of millet-seeds—*i e.*, grey granular tubercles, which I suppose this description denotes. That these tubercles have a linear arrangement, like strung beads, less abundant and less regular in the anterior part of the organ than towards the rete-testis, where they are closely set, and sometimes confluent; and that they undergo transformation into a yellow friable cheesy substance, which at a later period softens, and is often broken up into a curdy purulent fluid, the gland-structure being absorbed to give place to this tuberculous matter. But, if tubercles are deposited within the testicle itself, this structural change signifies little in

\* Diseases of the Breast, 1829, chap. viii.

† Diseases of the Testis, Curling, 1856.

reference to an early and exact diagnosis, for the "testis is often masked by small local effusions of fluid in the tunica vaginalis," the surfaces of which are partially adherent.

Now, the epididymis may remain nodose for many months; the nodules quiescent, or enlarging very slowly, and becoming painful. At length one declares itself more than the rest, attaches itself to the skin, which then assumes a purplish discoloration, ulcerates, and discharges a curdy purulent matter—the substance of the nodule. Other nodules undergo successively this process of disintegration, softening, and evacuation; but, unlike healthy abscesses, they do not heal. Fistulous openings obstinately continue to exude a mixed discharge—now curdy, now serous, now seminal; and in this advanced stage of the disease, destruction of more or less of the gland substance is inevitable. According to Sir B. Brodie's observations,\* occasionally one testis is completely disorganized; more frequently the organ is only partially destroyed, and a considerable portion of the glandular structure remains unimpaired. Sometimes the disease is confined to one testicle; sometimes both are similarly involved.

By this process of disorganization and protracted discharge the testicle is drilled and worm-eaten, as it were; so that eventually the organ collapses and shrivels up—a fragment only of its former self. There is seldom, therefore, any protrusion of gland-substance through the fistulous scrotum; on the contrary, in a favourable case the apertures gradually become inverted and depressed,—leaving, after the lapse of time, a puckered cicatrix, adherent to the remaining portion of the gland, as a lasting record of all this mischief.

*Blood-origin.*—In concluding this summary of many local diseases, which, possessing the same general characters, are fairly associated under the name of Scrofula, it is impossible to overlook at least two general facts that indicate their blood-origin. These diseases are perversions of nutrition in "many" textures and organs simultaneously; they "migrate" from one locality to another, and they are occasionally symmetrical. So, therefore, scrofula is, properly speaking, a blood-disease, and the diseases alluded to are local manifestations of a constitutional cause in operation.

*Blood-pathology.*—Nothing definite is known respecting the composition of the blood in scrofula. The blood is said to be rich in its amount of fibrin, but thin, of inferior plastic quality, and poor in its proportion of red corpuscles;—such is the result of analysis by Andral and Gavarret: that the "solids of the serum" are increased, and the "blood-globules" diminished, was the result of Dr. Glover's analyses;† and so on I might enumerate the conclusions of many other distinguished chemists.

*Causes.—Temperament.*—Certain bodily organizations evince a tendency to scrofula, and beget a suspicion that it will declare itself in some way, sooner or later. Individuals thus constituted are ever verging on this morbid condition, with threatenings of its outbreak here or there; but it must be confessed that no one temperament alone possesses the scrofulous character. It is the tendency of those whose circulation is habitually weak—are *leucophlegmatic*—who have flabby muscles, a dull muddy complexion, large heads, pigeon breasts, tumid bellies, and large joints; but then the strumous tendency is manifested in those persons also who, with a more active circulation, are rather of

\* London Med. Gazette, vol. iii. p. 377.

† Pathology and Treatment of Scrofula. Fothergillian Prize Essay, 1846, p. 115.

the *sanguine* temperament, have firmer muscles, a clear, transparent, ruddy complexion, which readily assumes a purple or livid hue by exposure to cold. The circulation, although active, is susceptible. Children, therefore, not uncommonly occur in children of this temperament; while their yellow or reddish hair, large lustrous blue eyes, crimson-patched cheeks, and pouting upper lip, are associated with that lively, impulsive, affectionate, and precocious disposition which so often raises hopeful expectations, never to be realized.

In contrast, however, with this organization and with these mental endowments, the same strumous tendency may be evinced in the highest degree by those who, without any marked character of circulation, are habitually subject to biliousness. In such persons the liver seems to be their weak point. Sluggish, yet enduring power is theirs also; and hair approaching black in colour, a dark olive or yellowish complexion, and dry skin, are aptly associated with a gloomy, often resolute, and reflective disposition. Theirs is the *melancholic* temperament. These are the chief signs of the scrofulous *diathesis*, although it *may* appear also in persons of the *nervous* temperament; and, indeed, the same tendency can be induced in those who are congenitally most indisposed to it when subjected to circumstances favourable to its development.

*Hygienic Conditions.*—Whatever impairs the nutritive qualities of the blood and its circulation may produce scrofula; therefore, deficient or defective food, indoor-life, insufficient ventilation, want of cleanliness and excretion, poor clothing, cold, damp, and even dark localities, with other *circumstances* of similar character, are the nurseries and nurses of this blood-disease. At the same time, *individual* predisposition, as usual, plays its part; for among a family of children in precisely the same hygienic circumstances, one becomes scrofulous, while the rest escape.

*Treatment.*—*Preventive* measures are far more efficacious than remedial treatment. They consist in the anticipation or timely removal of the predisposing hygienic conditions just adverted to; any inborn predisposition by temperament being beyond prevention. Due attention to food is primarily important. In the absence of more precise knowledge respecting the blood-condition in scrofula, it is impossible to direct and regulate the diet chemically. Experience, however, suggests a light nutritive diet, and not to overload the stomach by a heavy meal. Stimulants may be necessary to assist digestion, but they should be indulged in sparingly. The pampered scrofulous child of affluent parents is as badly off as the ill-fed child of the poorest. The bowels, which are very apt to be costive, or at least irregular in their action, will require the assistance of gentle aperients, such as rhubarb or the confection of senna. Not less important is daily exercise in pure air, and ablution not only to cleanse the skin, but to invigorate the circulation and promote excretion. Hence, sea-bathing may prove very beneficial. Friction with the horse-hair gloves and belt, or a rough towel, and warm clothing, with flannel next the skin, are likewise salutary. But, a warm, dry, light, locality for habitation, in a well-ventilated and well-drained dwelling, constitute the hygienic surroundings which are most preventive of scrofula. The latter, especially, is a hard prescription for the poor to carry out. Among, however, the many blessings bestowed on them in this vast metropolis, by the imperishable philanthropy of Mr. George Peabody, a yearly decreasing predisposition to scrofula, will perhaps be the greatest boon.

*Curative* treatment implies the same continued attention to the removal

of any causes provocative of this disease. The hygienic conditions of diet, exercise, air, ablution for cleanliness and invigoration, clothing, and climatic influence, are still of paramount importance. But certain medicinal agents, principally iron, iodide of potassium, bark, and cod-liver oil, have an acknowledged therapeutic value.

Iron may be given in the form of *vinum ferri*, the ammonio-citrate, the citrate or the sulphate of iron; the latter of which preparations I prefer, as it improves the blood more effectually. This is denoted by a notable arrest or diminution of any scrofulous deposit in the glands or other parts of the body.

Iodide of potassium has a beneficial influence on scrofulous deposit, apparently by promoting its absorption; but I must confess that this influence seems to me overrated. Iodide of iron is unquestionably remedial, but this is probably due to the iron rather than the iodine. Perhaps, therefore, the therapeutic value of iodide of potassium in scrofula, may be attributed to the latter ingredient; an explanation in harmony with the generally accredited efficacy of other preparations of potash in this disease.

Cod-liver oil, must be regarded rather as a food than a medicine; by supplying the proportionately diminished amount of fat in the blood, relative to the fibrin. It certainly has a most marked influence on scrofulous mal-nutrition. Cinchona bark, whether in the form of decoction or tincture, or quinine, is highly serviceable as a tonic in strengthening the circulation, and thence indirectly improving nutrition and all other functions. But it has no special influence on scrofula, and must be regarded as an adjunct to other medicinal measures. I am thus accustomed to prescribe the sulphate of iron in doses of three to five grains, with one or two grains of the disulphate of quinine, three times a day; coupled with a teaspoonful of cod-liver oil.

*Local* treatment has some effect on the *chronic enlargement of glands*, and of other parts, arising from scrofulous deposit. Applications of the compound tincture of iodine, or the stronger iodine-paint, may be advantageously aided in their stimulant operation by the pressure of strapping with soap plaster, or bandaging. Usually, however, these glandular enlargements will not subside, at least under topical treatment. When *abscess* forms, and discharges subsequently as an *ulcer*; these results must be treated accordingly. Much has been said about the virtues of caustic potash and other barbarous modes of apparently punishing a scrofulous abscess or ulcer; but there need be nothing peculiar in their local treatment, and it should ever be remembered that constitutional treatment can alone have any curative efficacy in scrofula.

*Operations* for scrofulous conditions of the bones, joints, or other parts, should be determined by the same consideration. Constitutional treatment will often succeed in averting the necessity for excision or amputation; a highly important consideration, since any local form of a constitutional disease is always an unfavourable condition for operation, and the removal of the part affected can in no way cure that disease as the primary cause. Hence, also, the postponement of such operation may not unfrequently be justifiable; and until the local condition becomes more defined, or its progressive extension renders operative interference imperative, whether with regard to the part affected or its reactive influence on the general health.

## SCURVY AND PURPURA.

*General Symptoms.*—Scurvy and Purpura are alike manifested by hæmorrhages into many textures, occurring contemporaneously or consecutively; and it will be readily imagined that these hæmorrhages occur with greater facility in some textures than in others. Into *cellular* tissue, for example, blood is very apt to escape. Such spontaneous hæmorrhages result from alterations which the blood itself has undergone.

SCURVY.—*Symptoms.*—The symptoms of scurvy may be well illustrated by a supposed case. A sallow and dejected-looking man, whose strength has been gradually failing, becomes the subject of hæmorrhages of a peculiar kind. The gums are turgid, spongy, and rotten; they ooze blood on the slightest pressure; the teeth loosen in their sockets and drop out. This fungous condition of the gums ceases abruptly at the reflexion of the mucous membrane to the lips, which are extremely pale, so also are the tongue, fauces, and inside of the cheeks. In some rare instances, however, this lividity extends nearly all over the hard palate. Red or livid spots are found—principally on the legs—together with bruised-looking patches, of a yellowish-green colour, swollen and hard as brawn.

Extensive effusions of *fibrin* rather than pure blood—forming very hard, broad, and painful swellings—are found imbedded in the deep cellular texture and between muscles. Over these fibrinous mats, the skin sometimes retains its natural colour, but usually appears bruised—is always thickened and brawny, and adherent to the subjacent textures. Swellings such as these occur particularly in the thighs and legs, but most commonly in the hams, occasioning stiffness and contraction of the knee-joint. Nodes also arise from this effusion taking place between the bones and their periosteal investment; the tight swellings formed thereby giving great pain upon the slightest motion, even by turning in bed. None of these effusions, whether of fibrin or blood, ever suppurate; nor do the nodes just mentioned, however large their size, ever cause the bone to exfoliate.

The dark livid or purple colour of scurvy overshadows any skin-eruption, wound, or ulcer, which may chance to be present during this disease. A dark grumous coagulum juts out from the surface of an ulcer; and this—which, owing to its appearance, has been named by sailors *bullock's liver*—often attains an incredible size in the course of a single night. To conclude the catalogue of hæmorrhagic lesions, repeated issues of blood from the nose are common; blood may be coughed up or vomited, lost by the bowels, and perhaps passed with the urine.

Scurvy is apt to prove fatal suddenly, from exhaustion. This remarkable feature in its career, with others of instructive moment, were exemplified in an equally remarkable manner during Lord Anson's expedition, 1740-44. The narrative states:—"Many of our people, though confined to their hammocks, ate and drank heartily, were cheerful, and talked with much seeming vigour and in a loud, strong tone of voice; yet, on their being the least moved, though it was only from one part of the ship to another, and that in their hammocks, they immediately expired; others, who confided in their seeming strength, and resolved to get out of their hammocks, died before they could reach the deck. It was no uncommon thing for those who could do some kind of duty and walk the deck, to drop down dead in an instant, on any endeavour to act with their utmost vigour; many of our people having thus perished during the course of this voyage."

**PURPURA.**—Similar *Symptoms* characterize Purpura, but there is not the same marked dejection and feebleness, nor are the gums always fungous. Extravasation of blood occurs in the form of small, round, purple spots, rather than parti-coloured blotches. These spots of blood are scattered in almost every texture. According to Sir Thomas Watson's experience,\* they are not peculiar to the skin, nor to the subcutaneous tissues, but occur occasionally upon all the internal surfaces also, and within the substance of the viscera. For example, on the mucous membrane of the mouth, throat, stomach, and intestines; on the pleuræ and pericardium, in the chest; on the peritoneal investment of the abdominal organs; in the substance of the muscles; and even upon the membranes of the brain, and in the sheaths of the larger nerves; and they may be accompanied with large extravasations of blood in most of the vital organs of the body. Such lesions are necessarily perilous. Bateman states that he witnessed three instances in which persons were carried off, while affected with purpura, by hæmorrhage into the lungs. Watson saw two post-mortem examinations, in both of which a considerable quantity of blood was found spread over the surface of the brain, between its membranes; and in one of these cases blood was extravasated also into the cerebral substance, with extensive laceration.

*Blood-origin.*—Scurvy and Purpura are *plainly* of "blood-origin." The blood itself spontaneously exudes, and appears as a bruise, yet without any bruising force having been applied. This hæmorrhage and ecchymosis takes place in many textures, and visits one after another. The whole organism, in fact becomes leaky, yet without the blood-vessels themselves being in any diseased state.

*Blood-pathology.*—*Scurvy.*—To what morbid condition of the blood must scorbutic hæmorrhage be ascribed? The blood has undergone remarkable and significant changes of colour; from the florid red of health, it has assumed a dark brown or green tint; it appears, also, only half coagulated, the supernatant serum being of a livid colour. Again, the red corpuscles are observed by Drs. Ritchie and Buchanan† to have become irregular in their outline, their disks more flattened, and more disposed to cohere together and aggregate into large insulated masses, than the corpuscles of healthy blood. These peculiar appearances are denied by other observers, who regard them either as inconstant or altogether absent. Dr. Garrod, for instance, affirms, that recent examinations have shown the blood not to be in a dissolved state, as was formerly supposed, but that the globules are normal in appearance, the clot firm and frequently buffed and cupped.‡

The balance of evidence, however, preponderates in favour of the characteristic colour and fluidity of the blood, and the collapse of the red corpuscles.

The chemical constitution of scorbutic blood is doubtful.

In the present state of Chemical Pathology, according to one authority, *potash is deficient*. Dr. Garrod's analyses§ lead him to conclude that the proportion of this alkali is reduced. Other authorities—Becquerel and Rodier||—find the proportion of *soda increased* in scorbutic blood, and that of *fibrin diminished*.

\* Lectures on the Principles and Practice of Physic, 4th Edit.

† Edin. Month. Journ., July, 1847.

‡ Ibid., Jan. 1843.

§ Ibid., 1848.

|| Pathological Chemistry, 1853.

*Treatment.*—*Scurvy.*—The *preventive* and *curative* treatment of this disease, is alike *dietetic*.

It is an undoubted fact that certain articles of diet possess anti-scorbutic properties. Lemon-juice is the grand anti-scorbutic, whereby thousands of persons have been rescued, who otherwise would inevitably have perished from scurvy. 1457 cases of scurvy were sent to Haslar Hospital in the year 1780. Subsequently, in 1795, lemon-juice was provided by order of the Admiralty, through the representations of Sir Gilbert Blane and Dr. Blair. Then only one case of scurvy appears in the hospital returns for 1806; and for 1807, one. Potatoes, whether in a raw state or cooked, are equally anti-scorbutic. Many other articles of diet, more or less in use, are enumerated by Dr. W. Budd,\* and their anti-scorbutic properties compared. So far, the prevention of scurvy is practicable.

But this kind of knowledge is *empirical*; we are ignorant (as Dr. Budd justly remarks) of the *essential* element common to the juices of anti-scorbutic plants, and in which their efficacy resides. Therefore, one plant cannot be substituted for another—prior to actual experience of its anti-scorbutic value—with the sure and certain prediction that it will prove equally efficacious, or more so. And why are we still ignorant of this “essential element,” and incapable, consequently of substituting an untried for a known anti-scorbutic? Because the “blood-condition” essential to scurvy is yet unknown, and that something, by virtue of which various plants are anti-scorbutic, is therefore equally unknown. Accordingly, the prevention of scurvy can be determined only by the results of actual experience.

Mark the further consequences of this empiricism. If *potash* were assuredly known to be the thing in question, it could be procured in almost any emergency from the ashes of any plant or of any wood, and especially, as Dr. Garrod has suggested, from that ubiquitous weed, tobacco, which is rich in potash.

In the present state of knowledge, the commissariat of an army, a navy, or commercial marine—ever liable to be placed in straitened circumstances with regard to all food—are in the dark on this most critical point. In encampments far from home, during sieges and long voyages, the allowance of lemon-juice has perhaps long been exhausted, and fresh vegetables are a dream; when, therefore, under these adverse circumstances, scurvy stealthily threatens, with pallid hue and dejected mien, the light of Pathological Chemistry would supply an unerring guide in search of that yet unknown something—be it potash or whatever else—by which the impending scourge would assuredly be averted. It might be possible, by a simple process perhaps, to extract that needful something from an abundant source at hand, in a locality otherwise well-nigh barren and desolate.

To conclude, on behalf of the prevention of this disease; any new and *untried* kind of food cannot be *substituted*, in an emergency, for another less plentiful; and, should all food run short, then the *essentially* anti-scorbutic constituent cannot be *extracted* from substances perchance close at hand, in which, like a precious pearl, it remains undiscovered, while scurvy is already overshadowing its victims.

Empirical experience is our only resource under these circumstances,

\* Library of Medicine, art. Scurvy.

and the rules which it authorizes for our guidance are necessarily of a very general character. They are enumerated by Dr. Budd as follows:—

Firstly.—Anti-scorbutic properties reside exclusively in substances of vegetable origin.

Secondly.—These properties are possessed in very different degrees by different families of plants; least so by the farinaceous, as wheat, oats, barley; most so by the succulent, as the *aurantiæ*, comprising oranges and lemons; lastly by potatoes.

Thirdly.—The anti-scorbutic property is impaired by the action of strong heat; nevertheless, boiled potatoes are anti-scorbutic (Dr. W. Baly); impaired, also, by vinous fermentation, but improved probably by acetous fermentation.

To show the difficulty of determining the essential treatment of scurvy empirically, I might add, in striking contrast, the conclusions of Dr. Christison in favour of *azotized* substances, and of *animal* origin, perhaps exclusively, such as milk.

These and similar discrepancies, on the part of practised observers, should direct the attention of chemists to the unknown “blood-condition,” as the only standard of comparison whereby to estimate the anti-scorbutic value of different substances, their composition being presumed to be known.

*Purpura*.—Although resembling scurvy in appearance, the curative treatment of purpura, by abstinence, purgation, and venesection, as recommended by the late Dr. Parry, of Bath, is altogether at variance with that which is so efficacious in cases of scurvy; and points, therefore, to some essential difference between these two diseases, otherwise allied. The manifestations of both are unquestionably of blood-origin, yet essentially different in this respect; and not until Chemical Pathology has determined the blood-condition *peculiar* to Purpura will it be possible to interpret rightly the whole etiology of this disease. Its rational preventive and curative treatment will follow.

## CHAPTER VI.

### RHEUMATISM AND GOUT.

**RHEUMATISM.**—*Symptoms and Diagnosis.*—Rheumatism is manifested by an inflammation affecting some portion of *fibrous tissue*; the ligaments and tendons around the joints, are more commonly selected, sometimes the fascia, and very probably the pericardium and endocardium. This inflammation is *specific*. It is denoted, just as common inflammation is expressed, by redness, heat, pain, and swelling; but rheumatic inflammation is characterized by not tending to the effusion of plastic lymph, nor to suppuration and gangrene; unless, indeed, some other texture besides fibrous tissue shares the inflammation, as synovial or serous membrane, when its products are the same as those of ordinary inflammation.

*Fever.*—This local condition is preceded by and accompanied with inflammatory fever, in perhaps its highest degree,—contrasting, therefore, in every way with fever of the typhoid type. A strong, rapid, hard pulse; headache without any delirium, excepting when pericarditis or

endocarditis ensues; acid perspirations and urine; these are the chief phenomena of rheumatic fever. And this fever not only precedes the local inflammation; but possibly runs its course without any such manifestation.

*Blood-origin.*—Rheumatic inflammation, whether exhibited by the joints, the fasciæ, or the heart, is evidently due to the operation of some morbid blood-condition; and for two reasons more especially.

The very fact of the same inflammation affecting, possibly, "many parts"—*e.g.*, many joints—simultaneously, points to the blood as its common cause. So also does the "metastatic" character of this inflammation. Passing from one joint to another—from the shoulders to the elbows, or from the knees to the ankles, perchance back again to the joints first affected, and probably thence migrating to the heart; these and similar alternations of the same character of inflammation betoken some morbid condition of the blood, which, as a reservoir supplying in common all parts of the body, is turned on, as it were, more abundantly (by inflammation), now on this part, now on that. The "symmetrical" distribution of chronic rheumatism,\* in many cases, affecting as it does corresponding parts of either half of the body, is further evidence of there being a blood-disease in operation; while such distribution exhibits also the elective power of similar portions of the same texture.

*Blood-pathology.*—But although the blood, vitiated in some way, is determined to the fibrous texture, by virtue of its elective power, we cannot say what particular ingredient, normal or foreign to the blood's composition, is appropriated thereby. The texture undergoing rheumatic inflammation selects something—but what?—from the blood.

Judging by the acid state of certain secretions—perspiration, saliva, and urine—during an attack of acute rheumatism, it would appear that an *acid* of some kind prevails in rheumatic blood; and, first suggested by Prout,† other authors,—Todd,‡ Fuller,§ C. J. B. Williams,|| Headland,¶ &c.—have since concurred in believing that this acid is *lactic* acid.

It is urged that, as the perspiration contains lactic acid, with lactates of soda and ammonia, and that exposure to cold, checking this secretion, is well known to be frequently followed by an attack of rheumatism; that therefore this disease is due to an accumulation of lactic acid in the blood. But then, sufficient exposure to cold ought invariably to have this effect; or—making allowance for individual peculiarities of constitution—at least in many instances such would be the effect of exposure. Moreover, the not unfrequent spontaneous origin of rheumatism in hospitals, where patients are protected from exposure, is irreconcilable with the theory in question.

Again, it is alleged that primary mal-assimilation—dyspepsia, in fact, of some kind—produces lactic in excess, which accumulates in the blood. But this theory also is not consistent with observation, so far as the absence of any symptoms of indigestion is significant.

Neither has it been demonstrated that lactic acid accumulates in the

\* Med.-Chir. Trans., 1842. Communication by Dr. W. Budd.

† Stomach and Renal Diseases, 1848, p. 84.

‡ Gout and Rheumatic Fever, 1843, p. 143.

§ Rheumatism, Rheumatic Gout, and Sciatica, 1860.

|| Principles of Medicine, 1856.

¶ The Action of Medicines in the System, 3rd Edition, 1859.

blood, as the product of secondary textural mal-assimilation; for chemical research has failed to discover any abnormal quantity of this acid in rheumatic blood. And this fact equally tells against the supposition of its accumulation by primary mal-assimilation, or by suppressed excretion of the perspiration.

Nor does *uric* acid superabound in rheumatic blood. Garrod's chemical analyses\* establish this negative fact. In truth, rheumatic blood is decidedly alkaline.†

*Treatment.—Preventive.*—The essential morbid condition—which, in those subject to rheumatism, is ever in operation as the cause predisposing thereto—being unknown, the evolution of rheumatic symptoms, from time to time, cannot be averted; and as if to show how comparatively unimportant, apart from this knowledge, is that of knowing the exciting and reputed cause of rheumatism, it is useless to avoid exposure to cold, for that alone will never evoke the disease, and if the blood be charged with the unknown poison, it will arise spontaneously.

*Curative Treatment.*—The same want of exact knowledge as to the nature of the rheumatic blood-poison, renders our remedial measures proportionately aimless. Whatever it be, there is probably—as with other blood-poisons—a natural tendency to elimination from the system by one or more of the excretory organs. Hence, it is not surprising, that experience should sanction the employment of medicines affecting the liver, and intestinal canal, the kidneys and skin.

In *acute* rheumatism—with high inflammatory fever—it may be necessary, in the first place, to reduce the general circulation by systemic blood-letting, venesection. Usually, however, a cholagogue dose of calomel, and an aperient saline, will prove sufficiently depletory, and remove also any source of irritation from the intestinal canal. But such measures are preliminary only. Then, the colchicum and alkaline treatment, is generally the most effectually anti-rheumatic. Bicarbonate of potash, in large doses—two scruples or half a drachm, combined with the wine of colchicum in doses of ten or twenty minims; may be administered every four hours. The joint-affections may thus subside within an average period of ten days, and the urine becomes alkaline. Sometimes the colchicum producing sickness and purging, it must be discontinued, or moderated; but it is desirable to keep the urine alkaline for two or three days after the joint-symptoms have subsided. This plan of treatment is certainly successful in many cases. In proportion as *synovial* symptoms predominate, or mix themselves distinctly with the fibrous—observes Sir Thomas Watson—in proportion as the disease approaches in its characters to gout, you may expect to be successful with *colchicum*. Dr. Garrod, who originated the *potash*-treatment in large doses, affirms that it greatly diminishes the tendency to pericarditis and endocarditis. Nitrate of potash—still in large quantity, half an ounce to three ounces a day—is the favourite salt with some practitioners; acetate of potash with others. The late Dr. Golding Bird trusted to the latter, given in quantities of half an ounce, much diluted, in divided doses, during the twenty-four hours. In three days only, it has been known to overcome the pain and inflammation, leaving the joints still swollen but placid. Iodide of potassium finds favour with yet other men of experience, surgeons chiefly,

\* Med.-Chir. Trans., vol. xxxvii., 1854.

† Ibid.

and lemon-juice has been advocated by Dr. Cwen Rees. Both the latter agents answer better in the *less* acute form of rheumatism. All these agents are probably eliminative, principally through the kidneys.

Calomel and opium, quickly pushed to slight salivation, is another plan of treatment. It would seem to be preferable in cases having a tendency to cardiac inflammation. Opium is, perhaps, most remedial in all cases of acute *fibrous* rheumatism. Sir Dominic Corrigan has great confidence in its efficacy. Beginning with one grain, repeated at short intervals in the twenty-four hours, he gradually increases the quantity up to an average of twelve grains during that period; and continues it until the disease declines.

In *chronic* rheumatism; the compound powder of ipecacuanha (Dover's Powder), guaiacum, and sarsaparilla, have reputed efficacy. It would be useless to extend the list. The general nature of the treatment of this disease,—acute and chronic, may be gathered from the foregoing observations.

*Local* treatment can scarcely be of any avail for a disease which, apparently, naturally expends itself by inflammation of whatever part or parts may become affected. Assuredly no repressive application can be salutary. Warm fomentations are calculated to lead the inflammation, as in all other cases, to an issue by resolution. Alkaline fomentations, and especially with an alkaline and opiate solution, are found to be even more conducive to this termination. Dr. Fuller, who strongly advocates such an application, usually employs a solution of carbonate of potash or soda, about half an ounce, in nine ounces of hot water, adding six drachms of liquor opii sedativus. Flannel steeped in this hot lotion is wrapped round the inflamed joints, and then encased with thin gutta-percha. Chronic rheumatism, attended with thickening and stiffness of the joints and fasciæ, may be somewhat ameliorated by warm baths, vapour baths, shampooing, or frictions. The Turkish bath will thus prove beneficial, provided there be no heart affection of consequence.

### GOUT.

GOUT is a blood-disease allied to rheumatism, but differing in its pathology and treatment.

*General Symptoms and Diagnosis.*—This disease is manifested by an inflammation affecting the joints, very commonly the first joint, or *ball*, of the great toe.

Commencing, usually, when the individual about to suffer has retired to rest, and has enjoyed some hours perhaps of sleep, he is awoken with fixed pain in one of his feet,—mostly, as I have said, in the ball of the great toe, but sometimes affecting the heel, instep, or ankle. With this pain, cold shivering is generally experienced, succeeded by heat, as the pain—boring, grinding, and wrenching—fastens more and yet more firmly on the spot of its election. “Place your joint in a vice,” said a witty Frenchman, “and screw the instrument up until you can endure it no longer. That will represent rheumatism. Then give another twist, and you will somewhat realize gout.” The skin over this part is acutely tender, red, tense, and shining, encircled by some œdema, and by converging turgid veins. Much restlessness and excitement supervene. In vain the sufferer seeks to relieve himself of the weight of his bedclothes upon the part inflamed; in vain he shifts his foot from place to place in search of

a cool and easy position. The pain, remorseless, grapples yet more tightly. At length, in the course of twenty-four hours or so, it loosens its hold gradually, perhaps suddenly. The sleepless excitement also then subsides, and the victim enjoys some temporary repose. He wakes again to undergo punishment. The toe-screw is reapplied, it may be with a turn or two less; and day by day a slighter punishment is inflicted, until at length the full penalty has been paid. The cuticle peels off the part affected, for gouty inflammation ends by resolution; it never terminates by the effusion of plastic lymph, suppuration, or gangrene. In these respects, this inflammation and that of rheumatism concur.

Eventually, after frequent attacks of gouty inflammation, the cellular texture around the joint usually becomes pervaded with a deposit of urate of soda, forming concretions, at first pulaceous, then "chalk-stones," of perhaps considerable size. The nodular fingers and toes of chronic gout is a matter of common observation. The skin over these nodules being stretched, at length breaks, and the chalky concretions are laid bare. Urate of soda has been found infiltrating all the textures of one or several joints, in synovial membrane, cartilage, the heads of bone, and ligaments; and usurping their place, the articulations are irreparably destroyed.\*

*Constitutional Disorder.*—Does any characteristic—*i.e.*, peculiar and constant, constitutional disturbance—precede and accompany an attack of gout? Yes, verily—and its *premonitory* symptoms refer to the functions of the stomach and kidneys, more especially. Dyspepsia, denoted by inappetency, eructations, heartburn, and acidity of the saliva; together with scanty urine, clear, high-coloured, and containing *less* than the average amount of *uric acid* or none at all; these symptoms portend a fit of the gout. An intolerable lowness of spirits, with general restlessness and peevishness are not unfrequently premonitory.

*Blood-origin.*—Chemical analysis demonstrates the presence of an *excess* of *uric acid*, with no other change, in the blood. It is, therefore, scarcely necessary to even glance at those characters in the history of gout which might otherwise be appealed to in support of its being a blood-manifestation. The absolute test of "blood-disease" having been supplied in this instance directly (by chemical analysis), supersedes the occasion of any other evidence. But I might point to facts such as these:—Gout visits "many textures" and parts of the body "simultaneously" or in "succession."

*Blood-pathology*—The blood superabounds with uric acid; but its normal constituents apparently are not modified. "It is," writes Dr. Garrod,† "by the augmentation of those principles which exist in health, in such minute traces as to be detected with difficulty, that the peculiar alteration of the blood in this disease is manifested. The blood in gout always contains uric acid in abnormal quantities and in the form of urate of soda, which salt can be obtained from it in a crystalline state."‡ It arises apparently, from mal-assimilation,—primarily, of albuminous food in the course of digestion, or secondarily, in the metamorphosis of muscular texture. Or, it may denote simply an excess of animal food over the wants of the system. And the fact first disclosed by Garrod's analyses

\* Diseases of the Joints, 1850, 5th Ed., Sir B. C. Brodie.

† The Nature and Treatment of Gout and Rheumatic Gout, 1859.

‡ Trans. Med.-Chir. Soc., 1848.

of the blood, coupled with the known phenomena of arthritic inflammation, inducing the formation of urate of soda concretions, and abundant deposit of urates in the urine; constitute a series of facts, which plainly declare the pathology of this disease. An attack of gout is an effort of nature—of the restorative power—to expel a poison, uric acid, from the blood. Sir Thomas Watson well describes this struggle. “Morbific matter (it may well be called a *poison*) is generated, or detained, under certain circumstances, within the body, and silently collects, in the blood; until, after obscure threats, perhaps, and prelusive mutterings, it explodes in the foot; and then the bodily economy, like the atmosphere after a thunder-storm, is for a while unusually pure and tranquil.”

Or, gout may engage many joints at once, or flit from one to another; or wander about, disturbing the heart, the lungs, and the brain. Hence palpitation and syncope, dyspnœa, disturbed vision and hearing, with cerebral commotion, bordering on apoplexy and paralysis. This is known as *irregular*, lurking, or masked gout. Sometimes, however, having settled in the foot, it suddenly disappears, and migrates to the stomach, heart, or brain; *retrocedent* gout as it is then called, being unlike the retreat of an ordinary foe—an assault on the very fortress of life. Less perilous migrations are witnessed, when gout betakes itself to the urethra, occasioning a scalding discharge; to the testicle, constituting one form of orchitis; to the eye, giving rise to ophthalmia.

All these manifestations of irregular and migratory gout should be borne in mind, otherwise, the disease in some form might be overlooked.

In whatever shape gout may have appeared, whether regular, disguised, or migratory, its decline is marked and measured by a flow of urine, surcharged with uric acid,\* thus relieving its accumulation in the blood.

*Detection of Uric Acid in the Blood.*—The ready method proposed and practised by Dr. Garrod for this purpose, and for which the abstraction of only a very small quantity of blood is requisite, he thus describes as the “uric acid thread experiment;”†—

“Take from one to two fluid drachms of the serum of blood, and put it into a flattened glass dish or capsule; those I prefer are about three inches in diameter, and one-third of an inch in depth: to this add ordinary strong acetic acid, in the proportion of six minims to each fluid drachm of serum, which usually causes the evolution of a few bubbles of gas. When the fluids are well mixed, introduce a very fine thread, consisting of from one to three ultimate fibres, about an inch in length, from a piece of unwashed huckaback, or other linen fabric, which should be depressed by means of a small rod, as a probe or point of a pencil. The glass should then be put aside in a moderately warm place until the serum is quite set and almost dry; the mantel-piece in a room of the ordinary temperature, or a book-case, answers very well, the time varying from twenty-four to forty-eight hours, depending on the warmth and dryness of the atmosphere.

“Should uric acid be present in the serum in quantity above a certain small amount, noticed below (*vide* Work), it will crystallize, and during its crystallization will be attracted to the thread, and assume forms not unlike that presented by sugar-candy on a string. This may then be examined

\* The characters of the urine in this, and other morbid conditions, are described in the ‘Urinary Pathology and Deposits’ of the Author’s Work on the “Irritable Bladder,” 2nd Edit., 1867.

† Op. cit., 1859.

by a linear magnifying power of about fifty or sixty, procured with an inch object-glass and low eye-piece, or a single lens of one-sixth of an inch focus answers perfectly. The uric acid is found in *rhombs*, the size of the crystals varying with the rapidity with which the drying of the serum has been effected and the quantity of uric acid in the blood." To ensure perfect success in this experiment, several precautions are necessary, for which the reader is referred to Garrod's Work, pp. 111-113.

An amount of uric acid equal to at least 0.025 grains in 1000 grains of serum, in addition to the trace existing in health, must accumulate before this experiment gives indication of its presence. *Premonitory* symptoms, however, coupled perhaps with the signal given by this test, announce that gout is impending.

*Hygienic Causes.*—Certain habits of life predispose to gout, and certain other habits of an opposite character have an opposite tendency. Indulgence in animal food more particularly, and stimulating drinks; generally, in point of fact, what is called "rich living," together with a sedentary, idle life; these are the acknowledged parents of gout; while moderation in the "pleasures of the table," even abstinence, with a life of active exercise, has no such offspring. Luxury and ease have long since been mistrusted as unqualified advantages compared with the apparent hardships of daily bread, earned by daily labour; so much so, that Abernethy's pithy advice, "Live on sixpence a day, and earn it,"—pointing, as it does, to the two elements, food and exertion, in relation to gout—has passed into a proverb.

*Treatment.—Preventive.*—The regulation of diet by exercise—of bodily supply by expenditure—is the preventive measure furnished by *experience*. But experience is insufficient for practical purposes. It affords no clue to the right understanding of the physiological relation subsisting between food and exercise, nor of the pathological relation between these hygienic requirements which determines the rational prevention of gout. It is the peculiar province of Science to supply the interpretation and elucidate the significance of facts. Knowledge thus becomes appreciated, and applied because appreciated.

Physiological Chemistry having first demonstrated the fact that all kinds of animal food, more especially, furnish uric acid in their transit through the body, by indigestion, or by metamorphosis of the muscular textures; it became obvious that the balance between the production and elimination of uric acid can alone be adjusted and regulated by a supply of animal food in proportion to its waste by bodily exercise.

Then Chemical Pathology contributed the additional and complemental fact, that uric acid existing as urate of soda in abnormal *excess* in the blood, is the *materies morbi* of gout. Obviously, therefore, the preventive measure which should be directed against such accumulation is this:—*To allow only that particular amount of animal food which, with daily exercise in proportion, will preserve the blood free from uric acid, short of the trace existing in health.*

Now this goes a step beyond mere experience. Guided by an exact knowledge of the *essential* morbid blood-condition from whence proceed all the phenomena of gout, we are enabled so to regulate the health as to prevent this disease. Exact information of the blood-condition, respecting any individual in question, can be readily obtained by abstracting a very small quantity of blood for analysis, or by examining the serum exuded under the application of a blister.

Moreover, by this *scientific* knowledge we are led to rationally administer certain medicines in aid of our hygienic preventive measures. Alkalies—of which the bicarbonate of potash is perhaps the most efficacious for prolonged use—may be administered daily, to neutralize any fresh accession of acid; and colchicum, as a diuretic, will aid the elimination of urate of soda by the kidneys. The mineral waters of Vichy, Wiesbaden, and other places of known repute, owe their virtue chiefly to similar qualities; but in speaking of the *principle* of prevention, I need not enter further into detail.

To illustrate the prophylactic management of gout, Dr. Garrod relates a case, on the authority of Sir H. Halford, in which colchicum with quinine taken in moderate doses daily, gave immunity for two years, when previously scarcely two months elapsed without an attack.

*Curative Treatment.*—Having due regard to the origin of the blood-disease,—by mal-assimilation, primarily or secondarily; hygienic measures are also curatively important. A reduced proportion of animal food is obviously the leading curative measure, and active exercise daily to increase the elimination of any excess is equally necessary.

No remedial measures are at present known for directly correcting mal-assimilation in respect to lithic acid or other products. The effect of increased bodily exercise may be to increase the destructive metamorphosis of the highly nitrogenous textures—*i.e.*, muscle, and thus directly increase the production of lithic acid: but this may also react beneficially in subsequently correcting the mal-assimilation.

Lithic acid passing off in the urine as lithate of ammonia is liable to be decomposed by the action of any free acid present in the urine; and lithic acid itself being insoluble appears as a deposit of reddish-yellow sand, consisting of crystals, which may aggregate and form a calculus. Hence the administration of alkalies to neutralize the acidity of the urine is indicated, of which bicarbonate of potash is, perhaps, the best for oft-repeated use. Other alkalies employed for this purpose are the bicarbonate of soda (“Vichy water”) the acetates, tartrates, and citrates of soda and potash, phosphates of soda and ammonia, and borates of soda and potash. Conversely, the removal of any source of acidity is also indicated; but this refers again to hygienic considerations. With regard to food, the vegetable acids, or that which will form them, as sugar or starch in the food, should, in Dr. Bence Jones’ opinion, be prohibited. On the other hand, free perspiration to eliminate the acids of the sweat, the retention of which would precipitate uric acid in the urine, is scarcely less important. Warm clothing, warm bathing, friction with horse-hair gloves and belt, an excellent stimulant, and diaphoretics, are most efficacious.

Lithate of ammonia being soluble in urine at the temperature of the body, its solution is thus secured, provided only that fluid be not overcharged. Dilution of the urine will best prevent supersaturation and deposit. The free use of aqueous drinks or soda water, is calculated to fulfil this indication, and thus probably prevent the formation of a lithate of ammonia calculus.

Diuretics, which increase the secretion, will also aid the dilution, of urine, and, moreover, will tend to eliminate lithic acid or lithates, from the system. The wine of colchicum, in doses of ten minims and upwards three times a day, prescribed with the carbonate of potass to keep the lithic acid in combination, the resulting lithates themselves being further

held in solution by the administration of diluents—will together carry off both, and soothe the irritability of the bladder which accompanies their discharge. Salient aperients seem to contribute to this desirable result. Any prolonged subjection to such a course of elimination, requires also the simultaneous action of small doses of blue pill, apparently to maintain the proportional secretion of bile, which otherwise being virtually retained as compared with the secretion of urine, would disturb the balance of their constituents in the blood.

## DISEASES OF CONTAGIOUS ORIGIN.

### CHAPTER VII.

By the term Contagion, I mean the communication of disease by external contact, as distinguished from communication by inhalation or infection. The disease produced is not necessarily constitutional, but possibly merely a local affection; for example, Itch, as contrasted with secondary or constitutional syphilis.

Still, under the same general heading may be associated certain remarkable species of blood-disease, which have severally received names of various kinds. Syphilis, Erysipelas, Pyæmia, Hospital Gangrene, Hydrophobia, Snake-bites, Malignant Pustule, and Glanders; are all naturally associated together as being contagious, or the offspring of contagion. But of these, the first four are derived from the *human* species, the remaining four from *animals*. This difference allows a corresponding division of the whole class.

#### SYPHILIS.

SYPHILIS is essentially a blood-disease, produced by the introduction of a virus or poison into the general circulation. But its introduction is attended by certain tolerably definite manifestations in the skin or mucous membrane, and proximate lymphatic glands, in the form of chancre and bubo respectively; constituting *local* or *primary* syphilis; while the consequent blood-disease is manifested by certain tolerably definite inflammatory modifications of nutrition in the skin, mucous membranes, eyes, testicle, periosteum, bones, and other parts—constituting *constitutional* or *secondary* syphilis. A concise description of this series of manifestations will lead to their diagnosis. How far *every* form of chancre and bubo, as local syphilis, may be *also* primary or *causative*, in relation to constitutional syphilis, itself necessarily secondary, will be duly considered subsequently.

LOCAL SYPHILIS.—(1) *Chancre, and its Diagnosis*.—Chancre is said to be a primary *syphilitic* sore or ulcer. Commencing at an uncertain period, possibly a month, but generally from three to five days, after infection; a trifling itching is experienced, affecting, usually, some spot in the furrow at the base of the glans penis, near the frænum, or it may be on the prepuce or the skin of the penis itself; there soon appears a small pimple, whose summit speedily becomes a vesicle, containing at first a thin transparent fluid lymph, gradually becoming thicker and opaque, in fact, purulent. If the syphilitic virus be introduced through a crack or abra-

sion, which may happen in the act of intercourse or have existed previously; the chancre forms as an ulcer, without any incipient pimple, vesicle and pustule; obviously because the cuticle there raised by secretion, was here removed. Otherwise, this papule, vesicle, and pustule, is alike the *typical* mode of origin of all chancres; yet how diversified their subsequent appearances, and how like those of ordinary ulcers. Their diagnosis is, perhaps, impossible. The granulating or healing sore alone excepted, we may recognise:—the simple syphilitic ulcer; the indolent and indurated; the irritable; the phagedænic; the inflamed; and the sloughing phagedænic.

When the pustule of an incipient chancre bursts, a “simple” ulcer is presented, without any special characters. It is a small circular cup-shaped cavity, having a smooth interior, without granulation, discharging a thin serous fluid, or glazed with a little adhesive lymph, and set in apparently healthy texture. This, the first of all primary syphilitic ulcers, may, however, about the end of the first week and never before the *third day*, become indurated, by effusion of plastic lymph beneath its base, and around. A single exception is observable in chancre on the glans penis, which never acquires induration; it is here simply a spot denuded of cuticle, and presents a red, moist, glistening, flat surface.

When “confined to the *base* of the ulcer,” such *induration*—elastic cartilaginous, and terminating abruptly—was regarded by Hunter\* as characteristic, and the specific diagnostic mark of true chancre. Yet Hunter himself acknowledged, in the sentence immediately preceding this, his definition, that the indurated base is not peculiar, being common to other indolent ulcers.

A slight modification, as it appears to me, of Hunter’s doctrine, has since been revived and advocated by M. Ricord,† who affirms that cartilaginous induration at the base, and *around*, a primary syphilitic ulcer, is absolutely *pathognomonic* of “infecting chancre,” or that species which accompanies and denotes constitutional syphilis. He regards this character as the local expression, by chancre, of the syphilitic blood-disease—in short, the first *secondary* symptom.

But precisely the same condition of induration may be produced artificially by irritating applications—*e.g.*, kali purum (Hennen), corrosive sublimate (Acton), and better still, says Ricord, by chromate of potash, or by nitrate of silver, the nitric and sulphuric acids; “so as to deceive even the most careful and experienced practitioners.” It was thus, for example, that Abernethy‡ was betrayed by an indurated sore, and recommended mercury to be rubbed in to salivation! Observing, however, that it produced no amendment, and ascertaining that the hardness had several times subsided and returned, an unirritating dressing was used, when the induration disappeared without the use of mercury.

Under other circumstances, pertaining rather to the state of the general health, and the condition of the digestive organs in particular, the primary ulcer becomes “irritable,” that is to say, painful and disposed to bleed easily. This, therefore cannot be considered a *specific* sore. Nor again is the “phagedænic” in any way characteristic. The same irregular worm-eaten sore, with sharp, undermined edges, may either be syphilitic, or proceed from the depraved constitutional condition by which a sore

\* Venereal Disease, edit. Home, 1810, p. 229.

† Lecture on Chancres, trans. C. F. Maunder, 1859.

‡ Surgical Observations, 1804, p. 135.

becomes phagedænic. Less characteristic is an obviously "inflamed" ulcer, and that mixed appearance known as "sloughing phagedæna." In short, the primary syphilitic ulcer may assume many characters, but none of them are *peculiar* to syphilis. Primary syphilis cannot thus be diagnosed with more than equivocal probability.

This *negative* result of observation is supported by the united testimony of all who during the present century have most patiently watched, in vain, to discover any characters whereby *chancre* can be surely distinguished. First:—Rose\* (1817), whose experience in the hospital of the Coldstream Guards ranged over a large number of cases, admitted that although there are many symptoms common to chancres, they are not entirely peculiar to them. Hennen† (1829) acknowledged with regret that there are "not any invariable characteristic symptoms by which to discriminate the real nature of the primary sore;" and, having witnessed many instances of self-deception, in attempting to diagnose a sore for the cure of which mercury is indispensable, from one of a different nature, he repudiated the pretensions of those who assume to themselves the possession of a "tactus eruditus" by which they can distinguish this kind of chancre. Recurring to the diagnosis of chancre, rather than the kind, Mr. Bacot's experience‡ (1829) led him to affirm, that chancre may present every variety of appearance to which a breach of surface is subject; and Colles§ (1837) stated, "as the result of long, attentive, and anxious observation," that primary venereal ulcers present an almost endless variety of character. To this effect also were the observations of Wallace|| (1838); for, says he, neither the mode of origin, nor the form, nor the colour, nor the size, nor the number of the ulcers of primary syphilis, are pathognomonic. Acton¶ (1851) avowed it was incontrovertible, that other sores, not of a specific nature, may assume all the aspect of real chancres; and Labatt\*\* (1858), considering the great variety of appearances presented by primary ulcers, experienced the difficulty of classifying them, and confessed that hitherto every such attempt had ended only in disappointment.

More recently (1860) Mr. H. Lee,†† recognises four varieties of Primary Syphilis—

First.—The inoculated part may become affected with the *adhesive* form of inflammation, in which lymph is poured out either in the substance or on the surface of the part.

Second.—The inoculated part may, within a few days of the application of the poison, be affected with *suppurative* inflammation.

Third.—The absorbents may assume an active share in the morbid process, and taking up some of the infected parts, and with them portions of the syphilitic poison, produce an acute inflammation of a lymphatic gland. This form of the disease is termed *ulcerative* inflammation.

Fourth.—The morbid action may terminate in *mortification*. Of this there are two practical subdivisions:—

(a) Death of the whole infected part, which is then thrown off as a slough; (b) Dissolution and death of a part only of the contaminated structure, leaving a part still infected.

†† System of Surgery, ed. T. Holmes, vol. i.

*Situation.*—The external parts of the *genital* organs are obviously the common situation of chancre, and some parts are more especially liable. Thus, in the *male*, that portion of the penis is commonly the seat of chancre, which having been exposed in sexual intercourse, is apt to retain any secretion with which it came in contact. Hence, the furrow between the glans and prepuce, and perhaps near the frænum is the most frequent situation; but chancre may form on the inner surface, or at the margin of the prepuce, or on the frænum; sometimes on the glans, or at the orifice of the urethra, or perchance on the skin of the penis. *Urethral* chancre is, however, not unfrequently met with; the chancre being situated immediately within the orifice of the urethra, or higher up in the canal. In the one case, it may easily be seen on just everting the lips of the urethral aperture; in the other case, it can be felt as a more or less nodulated induration of the urethra when pressed between the thumb and finger. Chancres thus situated have been found by Ricord to extend along the whole canal up to the bladder, in rare cases. Urethral chancre emitting its discharge from the external orifice, may be mistaken for gonorrhœa; but, while their diagnosis cannot be determined by the variable appearance of the discharge, inoculation will evince its true nature; a chancre being produced if the matter be syphilitic, and not by gonorrhœal discharge. The presence of a nodulated induration in the urethra will corroborate the diagnosis.

In the *female*, also, the external genitals are the common situation of chancre, as just within the labia minora; less frequently on the mucous membrane of the vagina, or on the os uteri or within the cervix. Examination will readily discover a chancre when situated externally; but, the speculum must be used to detect the presence of a vaginal or uterine chancre. In certain *unnatural* situations, chancre may occasionally be found; as at the anus, or on the lips of the mouth; suspicions of practices which need not be named.

(2) *Bubo and its Diagnosis.*—What is *syphilitic* bubo? Perchance its physical characters may be more uniform and peculiar, although available only at a later period than those of chancre, to guide our diagnosis.

Now it is alleged that bubo denotes absorption of the syphilitic virus from the primary sore, which, on its way to the blood, through the absorbents, irritates the absorbent glands, whereby they become swollen and hard, and perhaps suppurate. Compared with chancre, bubo can scarcely be called a *primary* symptom, for although the time of its accession after chancre is uncertain, it is always somewhat *later*. In many cases bubo *never* supervenes, the syphilitic virus apparently passing on uninterruptedly to the blood, without any demonstration during its journey, as if a highway robber should overleap a toll-bar without paying the customary toll.

This uncertainty respecting the formation of bubo, and delay in its coming, seriously impair its diagnostic value. On the other hand, bubo may possibly, although not probably, occur without previous chancre. Bubo may be the only primary symptom. Such buboes therefore have been named "primary buboes," and by the French "*bubons d'emblée*." Delpech, Sir A. Cooper, and many others deny their existence; whereas Fallopius, Hunter, Wallace, Lagneau, Swediaur, Bertrande, E. Wilson, and other authorities affirm that they do occur.

As being possibly the *only* primary symptom present, the question presses—are there any characters whereby *syphilitic* bubo can be assuredly identified? If no peculiar characters distinguish it, then bubo, no less than chancre, alone considered, is equivocal evidence in our diagnosis of primary syphilis.

Firstly.—There is the possibility of bubo arising from irritation of the lymphatics, in some part more or less remote; the irritation having apparently been propagated along the course of the absorbents leading to the swollen glands, without, however, any poisonous matter having been absorbed. The femoral glands becoming enlarged from the irritation of a chafed toe is a familiar illustration. This *sympathetic* bubo is easily distinguished by the kind of local cause in operation.

Secondly.—But if swelling of the lymphatic glands exist alone, unaccompanied and not preceded by any kind of sore, in any situation; then, is it possible to pronounce *that* swelling a syphilitic bubo?

Many species of bubo are attributed to syphilis, yet they all appear to be one and the same kind in different stages of progressive inflammation. Beginning as a hard and somewhat painful swelling of the lymphatic gland usually nearest to the spot whence the poison is absorbed; the absorbents themselves proceeding to the enlarged gland, share this inflammatory induration, and sometimes feel like hard whipcord. Along the back of the penis such cords may be felt leading to the groin, where mostly, just above Poupart's ligament, lies the swollen gland. Or, in the female, if a chancre be situated anteriorly on the vulva, this swelling is discovered at the external abdominal aperture; and if situated posteriorly, then betwixt the labium and the thigh, inflamed lymphatic vessels lead to a swollen hard gland in the groin. Occasionally bubo is situated elsewhere, when the vessels of absorption pass through other than the inguinal glands. Hunter saw a syphilitic bubo far down on the thigh; and he met with other instances on the lower part of the abdomen.

Wherever placed, as the gland enlarges it successively engages the surrounding cellular tissue and skin; the latter becoming inflamed and adherent, fixes the tumour. Suppuration *may* ensue. The skin acquires a stretched and shiny appearance, while the cuticle desquamates in receding circles, and the cutis becomes thinner. At some point fluctuation can be felt, the thin skin cracks, matter is discharged, and a cavity exposed that speedily assumes the condition of an ulcer.

Up to this point, the most critical observer could detect nothing to characterize the swelling syphilitic bubo, beyond the fact of its association with a sore, the nature of which, however, is itself doubtful; less certain, therefore, would the diagnosis be were bubo present alone. Carmichael\* acknowledges his inability, before ulceration, to determine whether bubo be syphilitic or not; and if the former, what *degree* of venereal disease; but that when ulceration takes place, the bubo partakes of the same mildness, or malignity, as the primary ulcer from which it originated. Yet these signs are equivocal, for, like chancre, the ulcer of an open bubo at once acquires all the characters of some kind of *common* ulcer; it may be the indurated and indolent, the irritable, phagedænic, inflamed, sloughing phagedænic. The size of this ulcer, of course, varies; usually not larger than the bubo itself, occasionally, and fortunately but seldom, it becomes enormous, extending inwards over the perinæum, or

\* Clin. Lectures on Venereal Diseases, 1842, p. 109.

downwards over the thigh, or upwards, perhaps, as high as the navel, while its depth may threaten the femoral artery.

Now all this—the origin and progress of an inguinal bubo—does not pronounce it syphilitic. Alone, its physical characters are fallacious—association with a sore elsewhere, the nature of which, as determined by its physical characters, is doubtful, renders the evidence only probable in some degree. Is there any *pathognomonic* sign or test which converts this indefinite probability into certainty?

*Inoculation.*—Does *Inoculation* supply the requisite test? The pus from a chancre, or bubo, being introduced beneath the skin of any part by a lancet charged therewith, produces a chancre. Thence in like manner another may be produced: first a pimple, then a pustule, then an ulcer. This power of reproduction was known to and used by Hunter. Mr. Lee affirms that inoculation, as a rule, is of no value in determining the nature of an infecting sore. That supposed instances to the contrary, as adduced by Dr. Sperino, were simply suppurating sores, with some amount of accompanying induration. But that out of 100 instances of indurated chancre, in one case only did inoculation succeed upon the patient who had the disease. On the other hand, Evans, Bell, Sperino, and other observers have alike insisted on the value of this reproductive test, and Ricord himself, who almost accords to “induration,” the rank of a pathognomonic sign of the “infecting chancre,” nevertheless regarding chancre as a distinct *species* of ulcer; acknowledges that its individuality “exists neither in its form nor in its floor, nor in an absolute manner in any one of its external characters. Its nature is in the pus which it secretes. Inoculation is the pathognomonic character of chancre, and which *alone* suffices to establish the diagnosis.”\*

Here then is an infallible test of *chancre*—the nature of its pus, as manifested by its inherent power to reproduce a similar ulcer—offspring and parent being alike, if under the same constitutional influence; and the offspring—chancre—inherits the power of propagation.

This method of diagnosis acquires a critical value from the fact established by Ricord, that the intensity of the constitutional manifestations about to ensue, cannot be measured by the number of chancres present simultaneously. Inoculation from a single chancre assuredly foretells any measure of constitutional perturbation; it is the brand of syphilis.

Then again, the power of reproduction is *inborn* in chancre, and available, therefore, as the test of chancre from the very first formation of lymph, when the chancre is yet a vesicular or pustular pimple. Inoculation is the *earliest*, as well as the most infallible, criterion of chancre. Thus also it contrasts favourably with induration, which is otherwise the most characteristic symptom, but which, in Ricord's experience, never precedes the ulceration; that generally towards the end of the first week following the infecting coitus, the induration manifests itself, and in the second week it becomes developed; but that while its development is rarely delayed until the third week, it is never met with earlier than the *third day*. The diagnostic advantage of inoculation, in point of timeliness, is apparently conceded by Mr. Lee; who thus qualifies his otherwise absolute rejection of this method of diagnosis. “A sore affected with the specific adhesive inflammation, will—he observes—yield a secretion capable of being inoculated during its *earliest* stage, before its specific

\* Op. cit.

action upon the patient's constitution has been developed, and the result of that inoculation may be a specific hardened sore accurately resembling the original. As soon as the specific adhesive inflammation has once taken place in a patient, his system is no longer in the same condition as before; he is no longer capable of being inoculated in the same way, and the inoculation, if attempted, in the vast majority of instances, entirely fails."

The bearing of all these considerations, on the treatment of chancre in relation to the prevention of constitutional syphilis, is obvious, and will have its practical application when I come to that branch of the subject.

What if this method of diagnosis, and the appropriate preventive treatment of constitutional syphilis, be postponed to a *later* period? Even then the open suppurating *bubo*, if present, is a chancre, and its pus will produce another chancre by inoculation. Not the pus secreted in the cellular tissue round about the suppurating gland, but that issuing from the gland. Here, then, is an *additional* test. We overtake the specific pus on its way to the blood, and possibly in time to anticipate its poisonous effects. Mere gonorrhœal bubo, or sympathetic bubo, arising from any irritation, does not yield specific pus; and the only question affecting the value of diagnosis by inoculation from bubo, is whether it affords a sufficiently early indication for the effectual employment of preventive measures.

Ricord observed that bubo, however large, which has arisen from a chancre when about to heal, is simply a swelling of the gland, and fails to supply virulent matter. The poisonous pus hitherto secreted by the chancre, was transmitted quietly through the absorbing lymphatics, without occasioning any outbreak in the glands; and now that they do offer some resistance, as it were, the pus still transmitted from the chancre is no longer specific.

But up to this time the *chancre* itself continues available for inoculation. The period of "*statu quo specific*" extends to when the ulcer cleanses itself, begins to throw out healthy granulations, and to cicatrize from its circumference. The duration of this period is considerable—frequently weeks, sometimes months; as long, therefore, as a chancre can be expected to continue without the supervention of constitutional syphilis, rendering any anticipatory diagnosis useless. In August, 1860, I had under my care a female patient in the Royal Free Hospital, who had previously an eruption on her skin, had then an ulcerated throat, and whose eyes presented, each, around the iris, a red zone bordering on iritis; yet with this train of secondary symptoms, two *specific* pus-secreting chancres still remained—one on either labium; and these, the patient stated, she acquired in December, 1859! No other chancres were present, nor were there any vestiges of others having been; and indeed, judging from her course of life since the time mentioned, when she was received back to a respectable home, it is probable that no sexual intercourse has since taken place. On this assumption these two chancres have continued specific during a period approaching *eight months*. Ricord maintains that the soft chancre, or that which he terms non-infecting, in a constitutional sense, mostly cicatrizes in the course of a few weeks; not unfrequently, however, the period of repair is prolonged much beyond; and that this form of chancre persists in preserving its virulent specificity almost up to the last moment of its existence; while, indeed, cicatrization

is proceeding at the circumference, the pus is specific in the centre of the ulcer; on the other hand, "the infecting chancre once developed, is not slow to limit itself, rapidly attains the period of *specific statu quo*, and passes with equal rapidity to the period of cicatrization."\*

The case I have adduced is apparently one exception at least to the invariability of M. Ricord's dictum, and the records of other observers are, I think, opposed to it. Of course the influence of different modes of therapeutic treatment must be taken into account; and of all differences in this respect affecting the results of statistics, the *mercurial* and *non-mercurial* treatment are the most influential. Subject thereto, I must allow that *some* of Rose's† well-marked indurated, or infecting chancres of Ricord—which were treated without mercury—conformed to the law laid down by the latter authority; they rapidly lost their specificity, for they rapidly healed. But such evidence of the short duration of the specific pus-forming power of this chancre is overruled by the history of thousands of other cases. Guthrie narrates cases treated without mercury, where the specific period, as measured by the chancre not healing, extended over six, eight, ten, and in one case twenty-six weeks. To the same effect are the very numerous cases endorsed by Sir James M'Grigor and Sir William Franklin.‡ In 1940 chancres taken indiscriminately, and which healed without mercury, the average period was, without bubo, twenty-one days, with bubo, forty-five days; and in 2827 chancres, including a larger proportion of indurated sores treated with mercury, the average period for healing was, without bubo, thirty-three days, with bubo, fifty days; (being a difference, I may remark, adverse to the generally supposed efficacy of mercurial treatment).

During a *long* period, then, extending to weeks or months, chancre retains its specific pus-forming power; and co-extensive therewith the inoculation test is available, so as to authorize our employing preventive measures against Constitutional Syphilis further than by local treatment, which is successful only when used during the first four days after the birth of chancre. And the *slow healing* power of a supposed chancre is itself corroborative proof of its nature. This character—signified by the absence of granulations—was long since observed by Hunter, and recognised by Colles,§ as a prominent feature in his definition of true chancre.

A self-reproducing and slow, perhaps very slow, healing sore or ulcer, is, in point of fact, a chancre; and while the latter character corroborates our exact diagnosis, it also provides a sufficiently early opportunity for the employment of certain preventive measures, after the first opportunity has passed away, in relation to Constitutional Syphilis.

What *its* manifestations are, will next engage our attention.

#### CONSTITUTIONAL OR SECONDARY SYPHILIS.

The blood, having become infected, after the appearance of induration, in the course of a month or six weeks, or a longer period, a constitutional disturbance—the syphilitic fever—ensues, usually in some degree. A dry, hot skin, and furred tongue, are succeeded by weakness and pain in different parts, with gradually the wan sallowness of syphilitic cachexia.

But, with the *accession* of this fever, various inflammatory modifications of nutrition occur, in a tolerably regular order, in different parts of

\* Op. cit.

† Med.-Chir. Trans., vol. viii. p. 558.

‡ Milit. Surg., Hennen, 2nd ed., p. 545.

§ Pract. Obs. on the Venereal Disease, 1837, p. 75.

the body. As manifestations of the blood-disease in operation, they are "secondary" or even "tertiary" to the chancre and thence the bubo, which, proceeding from the original source of infection, constitute "primary" syphilis.

The slow-healing power of the primary sore, and of an open bubo, somewhat suggest the prevailing character of these secondary manifestations. From the first moment of the pus-forming pimple, the whole career of syphilis is one of *disintegration* of the tissues, with an abortive effort of the reparative power by plastic lymph-forming induration. Disintegration by desquamative or other destructive eruptions of the skin; disintegration, by corroding ulceration of the tonsils, tongue, lips, palate, and perhaps the nose; disintegration, by iritis, with molecular lymph; disintegration, by irreparable destruction of the texture of the testis; disintegration, by caries and necrosis. Premature baldness, fretting ulceration around the roots of the finger and toe-nails, and a wan cachectic pallor, bespeak the consummation of syphilitic decay.

Comparing Secondary Syphilis in all these various forms, with similar diseases arising from other causes; their resemblance is often remarkable, and their appearances differ rather in degree than in kind. Probably, therefore, none of the manifestations of constitutional syphilis, secondary symptoms, are singly characteristic; but a concurrence—coterminously or consecutively—of such symptoms, may be diagnostic.

The descriptions given in Mr. Lee's elaborate treatise—for instance—with regard to syphilitic eruptions, for the most part amply confirm this general proposition.

(1) *Skin-diseases*.—Similar eruptions—exanthematous or rashes, papular or pimples, tubercular, squamous or scaly, vesicular and pustular—arise alike, as manifestations of constitutional syphilis in the skin; and also under other circumstances.

*Roseola or rose-rash*.—The eruption which usually first succeeds the syphilitic fever, is of a rose-red colour, not raised above the surface of the skin, disappearing on pressure, and returning as soon as the pressure is removed. It arises in the form of more or less rounded patches, giving a mottled appearance to the skin; when examined closely, each patch is seen to be made up of a cluster of papillæ, more injected than natural. This eruption sometimes vanishes within a few days. If it persists, the papillæ forming each patch generally become visibly enlarged, and the colour of the eruption gradually changes to a copper hue. This colour is commonly present in all syphilitic eruptions which remain for any length of time without suppuration or ulceration; but it is not peculiar to (secondary) syphilitic eruptions, it is not *pathognomonic*. It is—observes Erasmus Wilson\*—commonly met with in chronic eruptions of other kinds; for example, in acne, and non-syphilitic eruptions often possess more of the dull and muddy copper colour which is generally supposed to be characteristic of syphilis, than syphilitic eruptions themselves. Moreover, when present in undoubtedly syphilitic skin-diseases, it does not supervene until their decline.

The eruptions which follow this first efflorescence on the skin, present a variety of appearances.

*Lichen*, a papular eruption.—The papillæ of the skin are enlarged separately, in the form of hard elevations having a copper-colour, which

\* Syphilis and Syphilitic Eruptions, 1852, pp. 60-64.

terminate by desquamation or resolution. These elevations may be scattered irregularly over the body, or collected together into groups.

*Tubercular eruption.*—Effusion of plastic lymph having taken place, it becomes organized, as in the papular eruption, but now in the form of small, and tense conical eminences, covered with a red shining cuticle; which gradually acquire a copper tint, and shed their shining silvery scales of cuticle. The tubercles may be scattered singly over the surface, or aggregated into groups.

*Lepra, a scaly eruption,* commences, like the mottled skin of roseola, by the injection of circular groups of papillæ. The papillæ are at first separate, but soon the whole circular patch becomes equally involved; an effusion takes place into the substance of the skin, which then presents a small flat elevation, the edges of which are sometimes raised higher than the centre. A copper colour, of a more or less decided hue, overspreads the eruption, but it is often partially masked by a thin layer of cuticle, which is shed in thin white shining scales, as in common lepra. Numerous patches, all perfectly circular, may form on any part of the body. Patches of syphilitic lepra sometimes much resemble flattened syphilitic tubercles.

*Psoriasis*—another *scaly eruption*—occurs in the form of oval or irregular patches, slightly elevated above the surface. They are not depressed in the centre, and are often traversed by cracks or fissures. A copper or brown colour is often observable, but covered with epithelial scales of various degrees of thickness. This disease is much more persistent than syphilitic lepra. It occurs on the palms of the hands and soles of the feet, or on any part of the body.

*Vesicular eruptions*—as manifestations of constitutional syphilis, are similar to, if not identical with, vesicular eruptions not of syphilitic origin. Thus, in point of their origin only, we recognise *syphilitic herpes*, *eczema*, and *pemphigus* or *pompholyx*. In all, an effusion of serous fluid raises the cuticle into vesicles, or blebs,—*bullæ*, which are simply large vesicles such as occur in the last named form of eruption. But the diagnostic characters of syphilitic vesicular eruptions, are even less peculiar than those of the eruptions already noticed.

*Pustular eruptions* constitute also an analogous class to the non-syphilitic. They, like eruptions generally, may arise from the transformation of other eruptions, in the course of syphilis. Thus, the papular may change into the vesicular, and this pass into pustular.

The proper pustular eruptions of syphilitic origin, are divided by Cazenave,\* into three kinds:

(a) *Psyraceous* pustules, which are either small and narrow, or of large size, elevated, and round. They have a hard base, and are surrounded by a copper-coloured areola. The pustules are of a dull reddish hue, and are developed in successive crops; presenting examples of the disease in its origin, maturity, and decline. Their progress is slow, and the accompanying inflammation moderate. In some cases, however, it destroys the true skin, and leaves a small, white, circular scar, depressed in the centre, and not larger than a pin's head. This form chiefly occurs on the face and forehead, where it somewhat resembles *acne rosacea*, but it may appear on every part of the surface. The pustules dry into a small greyish scab, which separating, may leave either a cicatrix or some injection of the skin.

On the limbs, *psyraceous* pustules are of the size of a lentil, but

\* Diseases of the Skin. (Burgess.)

slightly elevated above the surface, with a hard base; and they contain a very small quantity of yellowish-white matter, which presents a strong contrast to the copper-coloured elevation on which it rests. They are not followed by ulcers; a thin scab forms on them, which is succeeded by a scar, or sometimes by a livid discoloration, or a small chronic induration.

(b) *Impetigo*, preceded by slight malaise.—This eruption commences with redness of the affected parts; then small collections of purulent matter form irregular shaped patches, more or less confluent, resting upon surfaces of a coppery-red colour, which are soon covered by scabs irregular in shape, harder, darker coloured, and more adherent than those of non-syphilitic impetigo. Beneath these scabs are characteristic ulcerations, followed by scars, varying in shape and extent. This eruption more frequently occurs on the face, but it may affect any part of the surface. It sometimes appears on several parts simultaneously, but it has no tendency to spread. It is always secondary.

(c) *Ecthyma*.—The pustules are still larger,—the size of a shilling, or more isolated, and few in number; chiefly occurring on the limbs, and especially the legs. Commencing as large livid spots, the epidermis becomes raised over a considerable portion of each spot, by a greyish, sero-purulent matter, which increases slowly, and is always surrounded by a broad copper-coloured areola, unlike the violet-red of non-syphilitic ecthyma. After a few days, the pustules having broken, scabs form, which are of a circular shape, dark and hard; gradually increasing in thickness they fissure at their edges, and are very adherent and persistent. On separating, they expose deep round ulcers, with sharp-cut hard margins of a purple colour, whilst the bottom is greyish. They have little tendency to enlarge. The scabs generally re-form, and repeatedly, until the ulcers heal; leaving circular and lasting cicatrices.

This is the most common form of syphilitic pustular eruption, and that which usually occurs in new-born children. Here, the pustules are broad, superficial, flat, of an oval shape, and in great numbers; the scabs are dark and thick, and conceal small ulcers underneath. The countenance of the patient has quite a peculiar appearance; it is drawn in, and marked with numerous wrinkles, like that of an old person; the skin has an earthy hue, the body is emaciated, and exhales a most disagreeable odour.

*Ulceration of the Skin* in constitutional syphilis, may be either a sequel of some form of eruption, or it may arise independently; the syphilitic blood-disease always predisposing to disintegration of texture. But the characters of the ulcers just formed can scarcely be regarded as peculiar to syphilis. Ulceration of the skin in connexion with disease of bone about the skull, is specially noticed by Mr. Lee, with reference to its apparent cause—irritation—rather than as arising from the direct influence of the syphilitic poison. The importance of this diagnosis, in relation to the appropriate treatment, is obvious.

(2) *Diseases of Mucous Membranes*.—*Ulceration of the tonsils*.—"sore-throat"—ranks among the earlier and less equivocal secondary symptoms.

The ulcer formed is excavated, with a sharp and prominent, not to say everted, margin. The bed of this ulcer is sloughy, the surrounding mucous membrane dusky red. But even these appearances are not characteristic of syphilis, and original observers, such as Rose\* and Carmi.

\* Med.-Chir. Trans., vol. iii. p. 421.

chael\* concur in mistrusting "the ulcerated sore-throat." Certainly, the excavated ulcer of Hunter is not consequent on the indurated chancre only; and we must acknowledge, with Carmichael, that affections of the throat are too indistinct to afford any certain diagnosis.

Fissures of, and *milky stains* on, the tongue and inside the lips are more pathognomonic, but the former must be distinguished from those cracks which accompany irritable dyspepsia, and the latter—opaque white spots—resemble aphthous spots.

More doubtful are *mucous tubercles* situated on various parts of the buccal mucous membrane, as the tongue, lips, palate and tonsils. These tubercles are of a whitish colour, and may be seen also on the skin, in the form of pale, soft little cushions, bedewed with mucus; the skin surrounding each tubercle appearing puckered around its margin. Such tubercles—condylomata—are commonly found in secondary syphilis, grouped around the anus or on the scrotum; also, fretting along the margin of the external labia in the female; perhaps on the perinæum, inner aspect of the thighs, and on the groins. Sometimes these tubercles occur in the axillæ (E. Wilson); and, in fact, wherever ordinary tubercles are warm and moist, they frequently become mucous tubercles, skin readily assuming the appearance of mucous membrane.

But mucous tubercles are not necessarily syphilitic. Wilson notices† the transition of roseola into lichen, of the roseola eruption into such tubercles, and that the conversion of lichen into them is by no means uncommon; yet roseola and lichen are not necessarily syphilitic eruptions.

"Ulceration of the *nasal* mucous membrane, that of the hard and soft *palate*, of the *pharynx* opposite the mouth, and of the *larynx*," may ensue in secondary syphilis. These ulcerations are frequently accompanied with caries of the nasal bones, of the hard palate, even the vertebræ behind the pharynx, and necrosis of the laryngeal cartilages. The breath and discharges are singularly fœtid. Is any such ulceration peculiar to secondary syphilis? Colles‡ acknowledges his inability to determine whether an ulcer in the nose be venereal or not. The appearances of scrofulous ozæna closely resemble those of venereal ozæna. Colles describes an ulcerated opening situated on the septum nasi, about a quarter of an inch from its anterior extremity, this ulcer being uniformly circular, and as large as the surface of a split pea; but adds, that a similar aperture may be found in persons who certainly never had any venereal affection, and that it may remain for years, at least for eight or ten years, in cases under observation. Extensive ulceration of the pharynx, as well as ulceration of the nasal mucous membrane and caries of the nasal bones, were noticed by Carmichael to be frequently associated with the primary phagedænic ulcer, but that similar ulceration of the pharynx arises in constitutional conditions assuredly not venereal. Chronic laryngitis, and ulceration of the rima glottidis, denoted by a broken voice, impulsive cough and foul expectoration, may be a manifestation of advanced and grave secondary syphilis. Portions of the laryngeal cartilages—*e.g.*, the cornua of the thyroid cartilage, in an ossified state, are occasionally coughed up. Sir A. Cooper mentions these extreme cases, in his Lectures; but syphilitic laryngitis presents nothing peculiar in its characters, from first to last, whereby it can be distinguished

\* Essay on Venereal Diseases, 1825, p. 64.

† Op. cit.

‡ Pract. Obs. on the Venereal Disease, 1837, pp. 305-316.

from chronic laryngitis ensuing under other circumstances. The symptoms just mentioned might follow laryngitis, from a common cold.

(3) "*Syphilitic iritis*" was overlooked by Hunter, in his observations of the course of the venereal disease; but although undoubtedly a frequent form of secondary syphilis, it cannot be distinguished from arthritic iritis; and resembles scrofulous iritis, in so far as regards the appearance of the eye itself.

An elaborate work,\* which still retains its rank, states that in syphilitic iritis the eye presents tubercular depositions of lymph on the iris, a reddish-brown discoloration of the iris on its inner circle, and an angular disfiguration of the pupil, which is also occasionally displaced towards the root of the nose; and that these appearances, coupled with nocturnal exacerbations of pain, experienced in a much slighter degree, or not at all, during the day, are together sufficient to complete our diagnosis, corroborated as it is by the previous occurrence of syphilis, and in most instances the concomitant existence of other syphilitic symptoms. I shall presently notice the diagnostic value of contemporaneous and consecutive symptoms, respecting secondary syphilis; but how far trustworthy are the objective symptoms afforded by those appearances which the eye itself presents? The authority I have quoted himself retracts in part the diagnosis he has laid down; for, says he, "although the effusion of reddish, brownish, or brownish-yellow lymph on the iris in the adult, clearly shows the case to be venereal, I have seen analogous appearances in several instances, both of young children and infants, in whom no suspicion of syphilis could be entertained." The symptom in question is not peculiar to syphilitic iritis. Nor is "displacement of the pupil upwards and inwards" a characteristic appearance. It has been seen, especially by Mackenzie,† in chronic rheumatic arthritis; and still more frequently in scrofulous sclerotitis, without iritis. Moreover, it is present only occasionally in syphilitic iritis. This symptom, therefore, is inconstant as well as equivocal. Mackenzie mistrusts all the special symptoms accorded to syphilitic iritis, excepting the *tawny* or *rusty colour* of the iris near its pupillary edge, a condition present in most syphilitic cases, and almost exclusively in them alone.

(4) *Chronic enlargement of the testicle*, occurs late, if at all, in the course of syphilis, and cannot be distinguished from scrofulous enlargement of this organ. The physical characters which the testis assumes in these diseased conditions are very similar. In both cases, the enlargement may commence in the epididymis—sometimes in syphilitic, generally in scrofulous disease. In both cases, this swelling subsequently engages portions of the testis itself, the intervening portions remaining free and healthy; so that sometimes, by careful manipulation, *nodules* can be felt in the substance of the organ, through the tunica albuginea. At length the whole testicle becomes considerably enlarged, and feels hard and heavy. Then the scrotum may become inflamed and adherent, eventually undergoing ulceration, accompanied with protrusion of the testicle. In one such case, at the hospital, the whole scrotum was so much thickened and discoloured that I removed the testicle together with the portion of skin chiefly involved, rather than endeavour to save the organ by partial excision. On section, the appearances were those of a scrofulous testis. The epididymis was filled with a yellow friable matter, which, under the

\* Diseases of the Eye, W. Lawrence, 2nd Edit., 1841, p. 428.

† Diseases of the Eye, 4th edit., 1854, p. 543.

microscope, was seen to consist of imperfect broken cells and granules; while nodules of this substance were deposited here and there throughout the testicle, itself otherwise healthy, the reddish-grey colour of its tubuli seminiferi contrasting with the yellow nodules. The man bore the mark as of a chancre at the corona glandis, which he says occurred about two years ago, and that the testicle began to enlarge nine months prior to the operation. Judging merely from the condition of the organ itself, in this case, it would have been almost impossible to have pronounced its enlargement syphilitic; and, indeed, the most accurate diagnosticians have acknowledged the resemblance of scrofulous and syphilitic disease of the testicle. Under whatever circumstances chronic enlargement of the testis takes place, the symptoms are precisely the same, observes Sir B. Brodie.\* Dupuytren, also, was led to this conclusion by his observations.†

Simple *glandular* enlargement or hypertrophy, and atrophy, of the testicle, are also noticed by some authors.

The *absorbent glands*, in various parts of the body, are liable to become enlarged, and indurated enlargement of those, especially on the occiput and back of the neck, is regarded by Ricord, I believe, as diagnostic of secondary syphilis. But this condition is attributed, by other writers, only to disease of the parts in communication with such glands.

(5) *Diseases of the bones, periosteum, fasciæ, and ligaments* are possible manifestations of constitutional syphilis, advancing from the surface to deeper textures within the body; but this is a neutral ground, shared by the mercurial poison—prolonged mercurialization, by scrofula also, and by rheumatism. The question of venereal origin is open, therefore, in every case, to investigation, probably, afterwards to doubt.

A truly syphilitic *node*, for example, is usually considered to signify merely chronic enlargement of the bone itself. A hard swelling forms, without any redness of the skin in the first instance, nor subsequently for some time; eventually only it becomes red and acutely painful. Such nodes occur mostly in certain situations. The syphilitic virus appears to select certain bones or portions of bones for the production of nodes; they are mostly subcutaneous, as the inner aspect of the shaft of the tibia, the subcutaneous portion of the ulna, the sternum, clavicle, and cranium. These portions of bone more especially form nodes, which become inflamed. Nodes arising from periostitis are softer, and evidently inflamed from their commencement. They suddenly arise, and as suddenly subside.

These distinctions are true, and yet the hard chronic node is no criterion of secondary syphilis. This kind of node seldom, if ever, appears, excepting when mercury has been used, and coming, as it does, late in the career of syphilis, has perhaps been preceded by more than one salivation. Issuing from the mixture of mercury and syphilis, one cannot say how far a chronic node is due to one or the other. It is no sure indication of constitutional syphilis. Carmichael's experience led him to regard this symptom as "equivocal and uncertain." Colles notices "a general nodose affection of the bones," which is liable to be confounded with so-called syphilitic nodes, and he draws some distinctions.‡

*Caries* and *necrosis* are no less doubtful evidence of constitutional syphilis. Spongy softening of the bones, denoting caries, may happen in

\* Lond. Med. Gazette, vol. xiii. p. 221.

† Clin. Chi., t. i. p. 100.

‡ Op. cit., p. 185.

an advanced stage of secondary syphilis, and has its chosen seats; these being chiefly those where nodes are prone to form—on the tibia, ulna, clavicle, sternum, and above all, the nasal bones and cranium. But whatever bone or bones undergo carious softening, there is nothing characteristic of syphilis. Mercury as well as syphilis may be at work; and indeed we rarely, if ever, find caries in syphilitic cases, excepting where mercury has been freely used. None of the cases of syphilis which came under the observation of Guthrie,\* in the York Hospital, were accompanied with caries; and such was also the experience of Rose, in his series of cases,† upwards of a hundred and twenty in number, and where he was able to ascertain that the patients remained free from syphilis for many months afterwards, or if secondary symptoms returned, caries was not one of them. Necrosis, in constitutional syphilis, is equally often the offspring of mercury.

*Tertiary Symptoms.*—All the foregoing diseases can scarcely be designated secondary. Some of them, and more particularly disease of the testicle and of the bones, are *tertiary*, as compared with others previously described in the series. So also are certain ulcerations affecting the *nose*, *lips*, and *roots of the nails*.

A tubercular nodule may form on the ala of the nose. It is a hardened copper-coloured mass, varying in size from the eighth of an inch and more; persistent perhaps for many months, then ulcerating and destroying the nasal cartilages, and possibly extending further.

Cracks on either lip may appear, and remaining for weeks or months, ulcerate extensively.

Ulceration about the roots of the nails, onychia, may occur, having a brown or black colour, surrounded by a deep copper-red margin, and attended with a most offensive discharge. The fingers, toes, or both, though commonly the former, may be thus affected. In either case the ulceration is very obstinate, and the nails loosen, or fall off.

The *hair* may become dry, withered, and faded in colour; cracked or split at its extremities, and be shed or easily combed off, abundantly, even to baldness. If the bulbs are affected, the hair is not reproduced, and the baldness is permanent, a condition known as *alopecia*. It may be partial or entire; and affect the beard, eyebrows, and eyelashes. In one case, recorded by Vidal, the hair over the whole body came off.

Syphilitic diseases of *internal organs*, apparently consisting of lymph-deposits, are, doubtless, highly important in the history of Constitutional Syphilis; but their diagnosis is mostly obscure, and needs much further clinical investigation.

Lastly, a wan, yellowish hue, overshadows the skin in an advanced stage of the disease, which is designated the syphilitic *cachexia*; but this may denote a mercurial deterioration of the blood.

**HEREDITARY, CONGENITAL, INFANTILE SYPHILIS.**—The term infantile syphilis is not intended to signify primary syphilis in an infant, communicated at birth, from a primary sore or chancre existing in the person of the mother. The disease referred to is truly constitutional syphilis inborn, and transmitted as an hereditary infection, from the mother at the time of conception or during the period of intra-uterine life. But constitutional syphilis in the mother, in the father, or in both parents, is not necessarily transmitted to the offspring; who may indeed be singu-

\* Med.-Chir. Trans., vol. viii. p. 560.

† Ibid., p. 422.

larly free from any manifest constitutional syphilitic taint, or any other evidence of impaired constitutional vigour—as scrofula.

Syphilitic infection of the *ovum* appears so to lower its vitality, as to entail many morbid consequences. Abortion may ensue, at a variable period of pregnancy, the ovum never reaching maturity. Several consecutive miscarriages may thus take place, until the maternal or paternal state of infection is rectified or eradicated; when the mother will probably retain the fœtus for the full period of pregnancy—nine months, and then give birth to a living child. From the time of birth, the infant may exhibit symptoms of secondary syphilis, and present a cachectic, weakly, dwindled, and as it were, aged appearance. Or, free from any secondary symptoms at birth, they supervene in a variable period—a few weeks, commonly between the third and eighth week—or, perhaps, not until adult age.

The *mode of communication* would appear to take place in either of four ways, or in their combinations:—(1) From constitutional syphilis in the father, and without communicating any apparent infection to the mother; (2) from constitutional syphilis in the mother; (3) from both parents; (4) from systemic infection of the mother, through a primary sore—a chancre, contracted during pregnancy—the embryo having been quite healthy at the time of conception.

The important relation of these modes of transmitting syphilis to offspring, will be obvious, both in regard to treatment and to medico-legal inquiry.

Many other questions pertaining to hereditary syphilis, remain open to doubt, and are disputed. *Firstly*, whether a mother, pregnant with a syphilitic fœtus, the offspring of a father having the constitutional disease, can be infected through it without herself having had primary syphilis? Ricord answers this question in the affirmative, and the possibility of this mode of maternal infection, is supported by a large amount of evidence collected by Mr. J. Hutchinson. *Secondly*, whether a wet-nurse, having the constitutional disease, can infect the child she suckles, through the medium of the milk? Yes, says Ricord; no, says Acton. *Thirdly*, conversely, whether a syphilitic child can infect a healthy nurse? No, say Ricord and Acton. But Hunter and Lawrence relate cases in which several nurses have been thus infected, in succession; and two of whom transmitted the disease again to their own offspring. Evidence in support of the affirmative of both the two latter questions, may be found in “Ranking’s Half-yearly Abstract,” vol. iv. As to the mode of communication by suckling; any crack or abrasion on the nipple, or on the lip or mouth of the child, will facilitate the transmission. But, according to Dr. Colles, mere contact, without any excoriation, will suffice.

*Symptoms.*—Hereditary syphilis is not indicated by any peculiar symptoms. The cachectic, wasted, condition of the child, usually attracts attention. Secondary symptoms are manifested by the skin, and mucous membranes—especially of the nose and mouth. Congestion of, and offensive muco-purulent discharge from the *nasal* mucous membrane, are accompanied with a puffed appearance of the nose, and constant snuffling breathing, as a chronic catarrh, existing from birth, or soon supervening. The mouth exhibits spots of ulceration. *Cutaneous eruptions* appear, before birth—the infant presenting some such eruption from birth, or not until some weeks have elapsed—usually three or four. It appears in certain parts, more particularly; about the mouth, on the nates or

scrotum, or on the soles of the feet. Hence, observation should always be directed to these parts, in examining an infant supposed to be the victim of hereditary syphilis. The eruption may be recognised in the form either of flat, squamous tubercles, associated with maculæ or spots; or as vesicles or bullæ, which dry into scales or scabs. A brownish-red, coppery colour, of, or around these eruptions, is more characteristic. The *teeth*, both temporary and permanent, are affected; the latter with a specific and peculiar appearance. According to Mr. J. Hutchinson's original observations, certain carious, or ill-developed appearances are presented. The *temporary* teeth are cut early, have a bad colour, and are liable to a crumbling decay. The upper central incisors usually undergo this destructive change early, and always first; then follow the lateral incisors, which become carious and are shed; lastly, though rarely, the canine teeth wear away, so as to assume a flattened, tusk-like character. Owing to early decay of the incisors, the syphilitic child remains edentulous from an early period, in regard to these teeth, and has a remarkably unsightly appearance in the laugh of childhood, until the permanent ones are cut.

The *permanent* teeth, are more peculiarly affected; chiefly the upper incisors, and first the central ones. They are discoloured, short, peggy, rounded at the angles; standing apart with interspaces, or converging; and marked, on their margin, with a deep broad notch. They readily disintegrate, crumble, and wear down.

VACCINO-SYPHILITIC INOCULATION.—A most important social question, is, whether a true chancre—an infecting syphilitic sore—can be communicated by vaccination,—through the vaccine virus? Dr. Viennois, in 1860, brought forward cases, apparently, of such syphilitic transmission; other cases subsequently occurred under M. Trousseau, in the Hotel Dieu; and, since, at Rivalta, an overwhelming demonstration occurred, one child, thus infected, having re-transmitted the disease to another child, and thence, through both, to forty-five other children, and to twenty other mothers or nurses!

DIAGNOSIS OF CONSTITUTIONAL SYPHILIS.—The presence of constitutional syphilis, as manifested by secondary symptoms, is determined solely by the calculation of *probabilities*; and this is the basis of diagnosis in respect to *all* diseases, excepting the few that are absolutely determined by pathognomonic signs. The diagnostic value of any one symptom is represented by the constancy of its presence and association with the same disease, and by the early period of its occurrence.

But the *co-existence*, or at least the *consecutiveness*, of symptoms, any one of which is equivocal, *per se*; constitutes a weight of evidence greater in the *aggregate*, than that which the *several items* of evidence would represent by being merely added together.

To illustrate this force of concurrence, by the evidence of secondary symptoms, I shall pass over the order of priority of these symptoms; thus overlooking the relative value of each, as an early symptom. No one secondary symptom is sufficiently constant or peculiar to syphilis, to make their *order* of succession a question of much practical interest. But the fact of these symptoms being concurrent in the same person, outweighs their inconstancy. Let the weight of *anti* syphilitic probability be represented by 5; then any one of the five usual secondary symptoms may be absent, or, if present, may point perhaps to constitutional syphilis, perhaps to the mercurial crisis, perhaps to both; perhaps

to neither of these blood-diseases, but proceed from other causes. Thus, the skin-eruption having a coppery hue; the excavated ulcer of either or both tonsils; iritis; enlarged testicle; node, caries, necrosis; are *severally equivocal* symptoms of constitutional syphilis; but taken *collectively*, or at least as *consecutive* symptoms, they *outweigh* the supposed anti-syphilitic counterpoise. Constitutional syphilis is diagnosed by an overbalance of probabilities in its favour—this overbalance being due, not to the actual diagnostic value of each symptom or probability, but to their concurrence. In like manner, other circumstances may tend to corroborate our diagnosis. The fact of primary syphilis, present or antecedent, has its weight—the weight of an additional probability, concurring. We look for the remains of a presumed chancre or chancres, and probably, also, the vestiges of a bubo or buboes.

The diagnosis of constitutional syphilis—thus clearly illustrating the diagnostic value of concurrent symptoms—is the species of evidence on which rests the diagnosis of most other blood-diseases; and, indeed, of diseases generally, the evidence of which is *symptomatic*.

The Blood-origin of symptoms, is established, in like manner, by concurrent evidence; but all the characters of blood-disease [P. p. 276] are rarely combined, or at least not in the same degree.

*Blood-origin of Secondary Syphilis.*—The evidence is, partly, the “number of textures” affected with some form of mal-nutrition—as of the skin, mucous membrane, iris, periosteum, bone and testicle; partly, the “migratory” character of these local affections—from skin to mucous membrane, to the iris, thence to the testicle, or to periosteum and bone; and partly, the “symmetrical” character of some such local affections; occasionally also, their “serpiginous,” or creeping nature, as phagedænic ulcerations of syphilitic origin. But the last two characters would seem to indicate some determining power in the *textures*, respecting the particular locality and form in which a particular blood-disease shall manifest itself. Lastly, syphilis is capable of being propagated by “inoculation.”

*Blood-pathology of Syphilis.*—Constitutional Syphilis shares the obscurity of other blood-diseases with few exceptions. The microscope exhibits nothing remarkable; chemical analysis, at present, brings nothing to light. The potent virus works unseen, being known only by the commotion it occasions. As when a diver has disappeared beneath the surface, we watch the troubled waters, without seeing *his* operations in the deep; likewise the syphilitic virus having dived into the blood, we know nothing of its doings there until it throws up some eruption on the skin or mucous membrane. Moreover, as the debris and bubbles thrown up by a diver cannot be distinguished from the commotion produced by some monster sporting in the deep; so also the scales and pustules of syphilis are subsequent and equivocal signs of the kind of poison at work. Meanwhile, its operation proceeds silently yet surely. The virus has not hitherto been detected in the blood; nor does inoculation with syphilitic blood manifest any characteristic results. Ricord failed to discover inoculable pus in the blood, even in veins nearest the chancre. MM. Ricord and Grassi first noticed “a decrease of the globular element in the blood of persons affected with syphilis arising from the simple or non-infecting chancre;” and indurated chancre also is apparently followed by a diminished proportion of globules, while the albumen increases. Yet these changes are not remarkable; and to discover *the* blood-condition

which precedes the local manifestations of constitutional syphilis, is still "a consummation devoutly to be wished." Rational Preventive treatment would then, and only then, be possible and practicable.

*Causative relation of Local to Constitutional Syphilis; and the Unity or Duality of the Syphilitic Virus.*—Of the various forms of Local Syphilis already described as Chancres, opinions differ respecting their causative relation to Constitutional Syphilis. It would be impossible within the limits of this part of the work, to discuss the evidence and arguments pertaining to this vexed question.

Ricord and his school, maintain that only one form of local syphilis—the *indurated* chancre—is the source of systemic infection; that it is the infecting sore, and that it invariably produces constitutional syphilis. But that non-indurated or soft chancre, is always a local disease, and is never followed by secondary affections. Hence, indurated chancre is the *only form of primary syphilis*.

On the other hand, other observers, scarcely less distinguished, maintain; that while the indurated chancre possesses the greater power of producing constitutional syphilis, and is thence the most frequent cause; yet that *soft* chancres may also occasionally have this causative relation. Hence, they also may be regarded as forms of primary syphilis.

My own experience inclines to this latter view of the relative infecting character of hard and soft chancres.

*Inoculation* throws some light on this question. The general results of inoculation in regard to syphilis, may perhaps be stated as follows:—

1. That a chancre always produces a specific virus.
2. That all chancres—hard and soft—are capable of being propagated by inoculation.
3. That inoculation with the serum or lymph from an indurated sore will only produce a chancre, and that an indurated one, when the system is unaffected. During, therefore, only the earliest stage of such chancre—*i.e.*, prior to induration, which may be regarded as the first secondary symptom.
4. That inoculation from an indurated sore—the system being unaffected—is invariably followed by secondary affections.
5. That inoculation from a soft chancre is less certainly productive of secondary affections.
6. Secondary syphilis may be propagated by inoculation.
7. But, that inoculation from secondary syphilis, is inoperative on the individual himself, or upon another individual having secondary syphilis.
8. That the secretion of other specific diseases existing in syphilitic subjects (including the specific syphilitic pustule, and the sores which result from it), have no power of imparting constitutional syphilis. (H. Lee.)
9. That the natural secretions of glands in syphilitic subjects, when those glands are not themselves specifically diseased, have no power of imparting constitutional syphilis. (H. Lee.)\*

If any of these propositions be erroneous, the error arises not simply from the difficulty inherent in the investigation of inoculation, but also from the difficulty of rightly estimating the mass of, apparently, contradictory evidence on this subject.

The *modus operandi* of chancre in producing systemic infection, is doubtful.

\* Holmes's Surgery, 2nd Ed., 1870.

The *lymphatic* or absorbent vessels were formerly regarded by Hunter, and his school, as the only medium of transmitting the syphilitic virus. Independently of the experimental facts adduced by Ségalas and Magendie, in evidence of the *veins* also being absorbents; there are two general facts which, apparently, disprove the absorbent function of the lymphatics, in the production of syphilitic systemic infection. (1) That in those cases in which the irritation of the lymphatics is greatest, and where, therefore, we have the best evidence that the morbid matter has entered them, there is very seldom any secondary syphilitic affection. (2) That the best marked cases of systemic infection are as rarely preceded by any very evident signs of inflammation of the lymphatic glands. In the first class of cases, moreover, the progress of the syphilitic virus may be traced along the lymphatic vessels as far as the first lymphatic gland in their course, but never beyond. In any part of this course, the poison may be arrested and produce a hard knotted cord or round induration, or even a fresh chancre; but there is no proof that the virus is conveyed unchanged through these glands; on the contrary, the vessels beyond are never affected, and bubo never forms in the glands next in order. Thus, chancre on the penis or vulva, induces bubo of the gland in the groin, above Poupart's ligament, but does not affect the vessels and glands within the abdomen; chancre on the finger affects the gland on the inner side of the biceps muscle just above the elbow, but not the axillary glands.

Duly weighing these facts, and the analogy of the syphilitic virus with other poisons, in producing systemic infection; Mr. Lee is inclined to believe that the syphilitic virus is communicated *directly* to the blood, through the nutritive changes of the part around a chancre, or point of inoculation.

**TREATMENT.**—*Local Syphilis.* (1) *Chancre.*—The earliest consideration, in the treatment of chancre, is the *prevention* of systemic infection; and the more so, since, in common with all blood-diseases, Syphilis is far more preventable than curable. Hence—observes Ricord—"the grand secret is, to reduce the specific ulceration to the state of a common ulcer, and to transform a wound possessing a special virus for its maintenance, into one which no longer has such a resource."

The earliest and most exact diagnosis of chancre, cannot, as we have seen, be determined by induration; but inoculation supplies the requisite test of specificity. Moreover, in relation to the most effectual known preventive measures, induration—occurring about the end of the first week, and never before the third day—supervenes too late for their effective application.

*Escharotics*, in Ricord's experience, are available within the first *four days* only, to prevent systemic infection,—you then kill the syphilis in its germ. Sigmund, of Vienna, also states as the result of his observation, in upwards of 1000 cases, extending over eleven years, that secondary manifestations never appear when the chancre is completely destroyed within the first four days. Cauterization to be thus effective, must be, not a slight superficial cauterization, which only destroys the surface of the ulcer, but a cauterization deep, broad, and destructive. We are dealing not merely with a poisoned wound, but with a self-producing poisoned wound. A paste consisting of sulphuric acid and charcoal, or stick nitrate of silver, will answer this purpose; but it must be applied over the whole sore and around, so as to include the infected peripheric zone of tissue beyond it.

By such local treatment alone can the chancre be converted into a simple healing ulcer,—in time to prevent *systemic* infection ; and it is also the surest prophylactic *socially*,—by extinguishing the *nuclei* of contagion. But, for either preventive purpose, destruction must be accomplished within the first four days after the birth of chancre. *Excision* of an *indurated* chancre has, occasionally, been practised ; but this method of removing the cause in operation, is like that by escharotics—too late when induration has taken place ; and excision offers no advantage over cauterization.

As a public preventive measure against the propagation of primary syphilitic infection, the “Contagious Diseases Act” for the periodic inspection of different classes of the community, was recently instituted ;—a similar legislative enactment to that which is in operation in France. As might be anticipated with reference to a procedure of such nature ; its expediency has been strenuously advocated from a sanitary point of view, and an extension of the Act urged, by numerous scientific supporters ; and it has been equally denounced, on moral and social grounds, by irreconcilable opponents. The Government has wisely declared its intention of abiding the result of the most complete inquiry.

The *curative* local treatment of chancre,—as a specific sore, is best accomplished by mercury. It may be applied in the form of mercurial ointment, spread on lint, and laid on the sore ; or as a lotion,—the *lotio nigra*, consisting of calomel and lime water, in the proportions of ℥j to ʒvj ; or, by calomel fumigation, locally applied, as suggested by Mr. Lee.

No other kind of *special* or specific treatment, is necessary with regard to chancre, than its early destruction, for the purpose of preventing *systemic* infection ; or curative measures, subsequently.

The various forms which chancre may assume, as the inflamed or phagedænic sores, are to be treated by the same measures which would be appropriate for similar ulcers otherwise arising

(2) *Bubo*.—No kind of *special* treatment is here indicated. If the bubo be an indolent, hard, swelling of one or more lymphatic glands, such as generally follows a systemic infecting sore ; no kind of preventive treatment will then be of any avail,—systemic infection having already taken place, and the bubo itself occasions little inconvenience ; if the bubo has suppurated and become an abscess, it is to be treated according to the course and tendency of other abscesses, not of syphilitic origin, and any consequent ulcer, in like manner.

*Constitutional Syphilis*.—*Preventive treatment* still claims our first consideration. After the limited period for the prevention of systemic infection, by the destruction of chancre, and before constitutional syphilis is manifested by any secondary symptom, there is yet an intervening period of blood-inoculation,—extending over about a month or six weeks, more or less, during which the development of constitutional syphilis may be intercepted. Otherwise, the blood will assuredly declare its noxious influence on nutrition, in due time ; by some secondary disease of the skin, by sore throat, iritis, and so forth. The impending evil is sure to supervene, in some form, the storm is sure to burst. There follows the *indurated* or infecting chancre,—says Ricord—a blood diathesis pregnant with misfortunes and tempests. An infallible explosion of constitutional affections will ensue.

But if some such manifestations are inevitable, in the natural course of systemic infection, all experience concurs, I believe, in the possibility

of averting them by medicinal intervention. By what particular preventive measures? Here opinions differ widely.

*Mercury* has long been, and is still generally, credited with the most potent prophylactic influence. The symptoms of its protective operation, constituting mercurialization, and the modes of administering mercury, will be noticed presently, in connexion with the curative efficacy of this medicinal agent. It appears indisputable; that if mercury be not preventive of systemic infection, no other known medicinal agent possesses such influence in any perceptible degree. The chief difficulty attending investigations, with reference to this question, is first to determine the natural course of local syphilis, in its *different* forms,—whether or not systemic infection would assuredly supervene; and thus, with corresponding certainty, to estimate the positive and negative results of mercurialization, or of other supposed protective measures.

*Remedial Treatment.*—*Mercury* holds the first place, and *iodide of potassium* the second, in the present anti-syphilitic materia medica. It would be impossible and useless to enumerate all the various remedies for constitutional syphilis, which have been tried and failed, more or less entirely. Such are sarsaparilla, guaiacum, opium, conium, juniper, sassafras, dulcamara, &c.

Mercury seems to produce a systemic condition which is antagonistic to, and incompatible with, constitutional syphilis, in most of the forms of its manifestation. And, indeed, this positively remedial operation of mercury, is rendered equivocal, only by the fact, that the natural tendency of syphilis to recovery requires further clinical observation.

The *symptoms* of the systemic influence of mercury, and of its sufficient operation remedially; are, a slight tenderness of the gums adjoining the teeth, with, perhaps, a slightly increased flow of saliva, factor of the breath, and a coppery taste in the mouth. But this degree of salivation must be maintained, until any secondary symptoms, whether as regards the skin, the throat, or the eyes, has entirely subsided; including also induration of the primary sore. Not until then can mercury be safely discontinued, with a view to the non-recurrence of secondary symptoms.

The *administration* of mercury is a matter of equal importance, and scarcely less so, the *kind* of mercurial preparations employed. It may be introduced into the system, through the gastro-intestinal mucous membrane, by pills or solution taken internally; or through the skin, by the rubbing in of ointment, inunction; or by exposure to vapour, fumigation,—mercurial bath; or, by inhalation.

Blue-pill—*pilula hydrargyri*, from three to five grains, two or three times a day; or calomel, a grain or more, in the form of a pill, and taken as often; have long been favourite forms of administering mercury. But these preparations are apt to produce irritation of the gastro-intestinal canal, and the liver, by their continued use,—occasioning bilious diarrhoea and sickness, long before their beneficial operation on the system can take place. Their introduction is, in fact, thus intercepted, and the mercury is said to “run off by the bowels.” A small proportion of opium—say, a quarter of a grain, combined with each pill, will tend to make the blue-pill or calomel settle on the stomach. The *iodide* of mercury, combined with opium in the form of a pill, is the preparation which I have long been in the habit of prescribing. It is less irritating to the stomach, and equally remedial. The *liquor hydrargyri bichloridi*, in half drachm doses, more or less, is a convenient form of administering mer-

cury internally; but I use it rather to sustain the systemic influence of the iodide.

Mercurial *inunction* supplies a more sure method of affecting the system, without any collateral disturbance of the digestive organs. It consists in rubbing in a small quantity of some mercurial ointment on the inner or thin-skinned aspect of the thighs, every night. A drachm of the blue ointment unguentum hydrargyri, may be thus continued nightly, until the gums are touched, and the secondary symptoms evidently subsiding. The ointment must be rubbed in until it disappears, and then the greasy surface should be left unwashed. This, however, is a laborious and dirty ordeal, an additional penalty for any one to pay besides having syphilis.

Mercurial *fumigation* may be preferable as a more cleanly and equally efficacious mode of introducing mercury through the skin. It consists in exposing the surface of the body, enveloped in a blanket up to the chin, to the fumes of some mercurial powder, which is heated until it rises in the form of vapour, and which can be advantageously associated with steam, as a vapour bath. For this purpose, an apparatus has been contrived by Messrs. Savigny. Or, a more ready contrivance, is a half brick, heated to a dull redness, on which the powder is placed, and set in a pan containing a little water. Calomel is the mercurial preparation generally employed; and fifteen or twenty grains, the quantity usually sufficient, will undergo volatilization, entirely, in fifteen or twenty minutes. The patient is then put to bed, so that the particles of calomel shall not be wiped off the surface of the body. This mode of introducing mercury is highly recommended by Mr. Lee, who observes that in his experience, neither of the other modes removes the symptoms so readily as calomel fumigation; none is attended by so little mischief to the patient's constitution; and none is followed so seldom by a relapse. He extends it, as I have already mentioned, to the local treatment of primary sores; and by means of a tube and mouth-piece, the vapour of calomel can be conveyed to the throat, for the treatment of secondary syphilitic ulceration affecting that part.

Mercurial *inhalation* can be administered by a simple and efficient form of inhaler, which is easily constructed; a common earthen tea-pot, to the spout of which is attached a tube of vulcanized india-rubber, about a foot long, and provided with a bone mouth-piece, in shape like the amber of a meerschauu pipe. A scruple of calomel is placed in the tea-pot, and the little hole in the lid which allows the escape of steam, is stopped with a peg of tightly rolled paper,—better than wood which yields and loosens in driving it in. The pot thus equipped is ready for use. Resting on an iron tripod stand, the bottom of the pot is exposed to the flame of a spirit-lamp, placed sufficiently near, so that the flame shall expand under the whole bottom. In two or three minutes, the calomel begins to pass into vapour, and, the lid having been raised for a moment to ascertain that fact, the patient is told to inspire through the mouth-piece, at the same moment closing his nostrils between his thumb and fore-finger, then expire through the nostrils; and so on alternately, breathing in a naturally free and easy manner. After about ten or fifteen minutes, all the calomel will have been inhaled as vapour, save a small quantity which adheres as a thin, white film to the interior of the pot and tube.

In two cases wherein I have resorted to the inhalation of calomel-vapour for the treatment of secondary syphilis, with ulceration and

sloughing of the throat, the tea-pot inhaler, I improvised, having been used, the following facts are worthy of notice for guidance in general.

1. In both cases, previous treatment by mercury, and iodide of potassium, administered by the mouth, had been tried, successively, and failed; and, in one case, it was impossible thus to continue the treatment, these medicinal agents being absolutely rejected by the stomach with nausea, and constantly recurring sickness.

2. The gradual process of inhalation,—ten or fifteen minutes, and the quantity used, twenty grains.

3. Explosive coughing after inhalation,—variable in period of sequence, in its degree, and duration, but subsiding spontaneously and permanently. This might be moderated by reducing the quantity of calomel to, say half—ten grains, while the same beneficial influence might be gained by repeating the inhalation.

4. Slight salivation, in about forty-eight hours, and disappearance of the secondary symptoms; ulceration of the throat, especially.

5. Compared with mercurial inunction, and with the mercurial bath; the inhalation of calomel vapour, is more speedy and effectual, in its systemic influence, than the one, and far more so than the other.

6. As to safety; in one of the two cases, the patient died, some days after inhalation, from bronchitis and pneumonia, but the patient had a very feeble venous circulation, and his constitution had been worn out by an Indian climate, and great intemperance, more than by constitutional syphilis. In the other case, the pulmonic effect of inhalation was inconsiderable, and the process was repeated on four different occasions, without any danger.

The *balance* of evidence, from these two cases, is therefore, in favour of inhalation; and, relatively also to mercurial inunction, and the mercurial bath.

*Excessive mercurialization* produces symptoms which it may be convenient here to notice. They are; profuse salivation, swelling of the salivary glands, gums, tongue, and face, ulceration of the mucous membrane, loosening of the teeth and even necrosis of the jaws. Diarrhœa, with bilious evacuations. Certain varieties of skin diseases;—*e.g.*, mercurial eczema. Periostitis and ostitis, otherwise than connected with the mouth. Low fever with great prostration or mercurial erythism. Nervous affections;—*e.g.*, neuralgic pains, partial paralysis, or mercurial tremor, sometimes complete paralysis and death; usually observed in those subject to the action of mercurial fumigation.

*Iodide of potassium*.—Not to be trusted for the prevention of constitutional syphilis, ranks next to mercury as a curative agent; and especially in some forms of the disease, and in a certain constitutional condition, whether natural to the individual or morbid, where the action of mercury cannot be borne. It may be stated generally, that in the forms of skin-eruption accompanied with plastic induration, in the earlier period of constitutional syphilis, and in young and vigorous subjects, mercury is most curative; whereas, in pustular eruptions, enlargement of the testicle, periostitis and ostitis, and any tertiary affections, in the later periods of syphilis, and in debilitated, cachectic, subjects, iodide of potassium is the more remedial. But, perhaps, it may be added, that its effects are less permanent than those of mercury, and thus the disease is liable to recur. Iodide of potassium is given in doses, usually from three to five grains, thrice daily, and combined with cinchona bark, cascarilla, or other

vegetable tonic; this adjunct generally being requisite under the circumstances of suppuration or ulceration, wherein the iodide is prescribed. This medicinal agent was, I believe, originally brought into use for the treatment of constitutional syphilis, by Mr. Samuel Cooper, Mr. Morton, and other Surgeons at University College Hospital, about the time when I was a Student in that Institution; and it has since found much favour with the Profession. I have prescribed it with marked advantage in some thousands of cases, principally at the Royal Free Hospital.

Iodide of *mercury* has considerable repute with many continental surgeons; a grain being given in a pill three times a day, and gradually increased to three grains. Or, this combination may, probably, be effected in the system, by the concurrent administration of iodide of potassium or iodide of sodium, while mercury is introduced through the skin; thus obviating any irritation of the digestive organs which might be excited by giving the iodide of mercury itself.

*Sarsaparilla* has far less influence on constitutional syphilis than was formerly supposed, within my recollection. Its therapeutic value would seem to be restricted to the more asthenic or later secondary, and tertiary symptoms, and as occurring in debilitated subjects; the same circumstances which render iodide of potassium preferable to mercury. Or, again, mercury having produced a new series of symptoms simulating the syphilitic, sarsaparilla will then be remedial; or it may come into use at a subsequent period, to remove the *sequelæ* of a mercurial course. Sarsaparilla is thus, on the one hand, a substitute for iodide of potassium; or, on the other hand, an anti-mercurial. The decoction is the preparation usually employed, but it must be concentrated, and drank freely; in not less quantity than a wineglassful three times a day. It may be advantageously combined with iodide of potassium; the two forming what has been indefinitely named, an "alterative" mixture. Sarsaparilla has also a tonic influence, but less so than bark, and it is said to be diuretic and diaphoretic. This compound influence may give sarsaparilla an advantage over the more purely tonic operation of bark, when given in combination with iodide of potassium.

*Guaiacum*—another overrated medicine in relation to constitutional syphilis—is nevertheless, apparently, beneficial under similar circumstances to those which render sarsaparilla—and iodide of potassium—preferable to mercury; particularly in secondary affections of the periosteum or bone, and as occurring in cachectic subjects; or it may be useful in clearing off the effects of mercury. The stimulant and diaphoretic actions of guaiacum may, perhaps, explain its therapeutic influence in the course of secondary syphilis, and as an anti-mercurial.

It would be of little practical importance to enlarge this general view of the medicinal treatment pertaining to Syphilis. Excluding the many nostrums which, from time to time, have had a temporary remedial reputation; the details of the course of treatment, with reference to the various forms of skin eruption, and other secondary, and tertiary, syphilitic manifestations; can alone be taught at the bedside, or learnt by experience.

The pathology and treatment of Syphilis are thus summed up by Mr. Lee.

There are four varieties of local syphilis, resulting from the inoculation of the syphilitic virus, which are quite distinct, although they may occasionally succeed each other.

The *first* variety is accompanied by the adhesive inflammation, and produces a peculiar chronic enlargement of the inguinal glands, which does not involve the skin or the cellular membrane. This variety is followed by secondary symptoms, and requires, both in its primary and secondary forms, mercurial treatment.

The *second* is accompanied by suppurative inflammation. It does not affect the inguinal glands. It is not followed by constitutional diseases, and requires merely local treatment.

The *third* is accompanied by the ulcerative inflammation. It produces suppuration, generally of one inguinal gland only, which yields an inoculable secretion. It is not followed by constitutional syphilis, and may be treated by local means.

The *fourth* is accompanied by mortification. It does not affect the inguinal glands, is not followed by constitutional symptoms, and requires only local treatment.

*Syphilization* yet remains to be noticed. It is said to be the *curative* treatment of constitutional syphilis by repeated inoculation with the syphilitic virus, and for the *prevention* of its recurrence. Syphilization is also practised for the cure of primary ulcers, under the influence of which it is said they soon lose their hardness and begin to cicatrize. Buboes are thus affected beneficially. Vegetations remain uninfluenced.

This method of treatment, originated by M. Auzias-Turenne, about 1845, and adopted by M. Sperino, is specially advocated by Professor Böeck, of Christiania, with reference to constitutional syphilis; and, in 1865, he visited this country to inculcate his views by practical illustration in the Lock Hospital. The matter from a primary syphilitic ulcer, hard or soft, the former being preferable, or that from the artificial sore of a patient undergoing syphilization, is inoculated or introduced, in the same way as vaccine matter. To prevent large ulcers and cicatrices, the inoculations are commenced on the sides of the trunk. Three inoculations are made on each side. After three days, pustules will have formed, and from these, other inoculations are then made. This is repeated every third day, the matter being always taken from the last pustules, until no further effect can be produced with this matter. Fresh matter is now introduced, from another patient; pustules ensue as from the matter first used, but the pustules and ulcers resulting from this second matter are not nearly so large as those originally produced. A third matter elicits pustules and ulcers yet smaller and fewer in number; until, ultimately, no matter applied to the sides will produce any specific effect. But, the arms and thighs are still susceptible to inoculation, either from fresh matter or from matter of the last pustule. The process is therefore now repeated on these parts in succession, until there also an immunity is obtained. Ordinarily, this occurs in from three to four months.

The conclusions arrived at by Professor Böeck are:—

- (1) That artificial chancres on the sides and on the arms are always smaller than those on the thighs, and the series of inoculations shorter.
- (2) By continued inoculation the ulcers always become less and less, until at last inoculation gives a perfectly negative result.
- (3) The inoculated individual grows insensible to one matter, but is still susceptible to another, yet in a lower degree; and again to a third matter, but in a still lower degree; and so on until no further effect is produced by any matter.
- (4) Immunity having been obtained on the sides and on the arms, it

will still be possible to have rather a long series of inoculations on the thighs.

All these phenomena are said to be constant; they do not occur in one individual and not in another; they will always be presented. "We have here an invariable law of nature."

A *saturation* of the system with syphilis—according to MM. Auzias-Turenne and Sperino—is thus established; a syphilitic *diathesis*—according to Dr. Böeck—which, when once established, cannot be increased or intensified by the further inoculation of virulent matter. But the continued insertion of this matter, stimulates the disease and enables it to pass through its regular course; thus completing the series of phenomena which follow systemic syphilitic infection, in a *far shorter period* than if left to itself, or subjected to any other method of treatment. Relapses and the occurrence of the so-called tertiary disease, are therefore rarely found after this curative treatment; whilst the continued introduction of syphilitic matter into the system, destroys, in a varying period of time, the susceptibility of the individual; ultimately producing a local as well as a general immunity to the disease, which constitutes its preventive treatment.

Patients of all ages, even very young infants who are the subjects of *hereditary* disease, have undergone this course of treatment. In the latter, however, inoculations will frequently not take effect; nor in persons with acquired constitutional syphilis, who, at the same time, are suffering from some acute or debilitating disease. But the latter adverse conditions are temporary, and immunity is generally obtained. Its duration in regard to the local action of the virus is limited, freedom from susceptibility to the production of chancre being gradually lost after the inoculations have been discontinued; but the systemic immunity continues, and frequently throughout the life of the patient.

These results have been attested, it is said, by some hundreds of cases.

It is admitted, however, that the success of syphilization is very much modified by the fact of whether, or not, the patient had previously undergone mercurial treatment. Dr. Böeck alleges that mercury interrupts and retards the natural course of syphilis, and that, in like manner, it interferes with its treatment by continued inoculation,—thus diminishing the curative efficacy of syphilization.

It was at this stage of the inquiry more particularly, that syphilization was tested at the Lock Hospital, in 27 cases, under Dr. Böeck's immediate supervision. Mr. James R. Lane, and Mr. Gascoyen—the surgeons to that Institution—have supplied an elaborate Report\* of these cases; which, while it contributed interesting particulars on points connected with the clinical history of syphilization, and indirectly with the pathology of Syphilis, condemns it as a method of treatment. On this aspect of the question, the report concludes:—"We are entirely in accord as to the practical bearings of Syphilization, and we are decidedly of opinion that it is not a treatment which can be recommended for adoption. We consider that, even if it could be admitted to possess all the advantages claimed for it by its advocates, its superiority over other modes of treatment, or in many instances over no treatment at all, would not sufficiently compensate for its tediousness, its painfulness, and the life-long marking which it entails upon the patient.

\* Med.-Chir. Trans., 1867.

"If Syphilization could be relied upon, after other treatment had failed, to control the severer forms of the disease, especially in its tertiary stage, or to prevent its hereditary transmission, the benefit derived would, without doubt, more than counterbalance these disadvantages; but unfortunately these are precisely the cases in which it has admittedly the least influence."

## CHAPTER VIII.

### ERYSIPELAS.

ERYSIPELAS is a blood-disease, manifested by a peculiar inflammation of the skin, and subcellular texture, possibly also of the mucous membrane; and of an infectious character. The latter element of this definition is disputed, and indeed open to doubt.

Any such doubt, and disputation, seem to have arisen from one oversight—that of associating erysipelas, as a peculiar inflammation of the skin and subcellular texture of the *head and face only*, with *erysipelatous inflammation* of the skin and subcellular texture of any other part of the body. The former is decidedly infectious; the latter, apart from co-operating causes, less decidedly so.

*Simple Erysipelas.*—Commencing in the integuments of the head and face, simple erysipelas exhibits the following characteristic appearances:—On the nose, either cheek, the margin of either ear, or sometimes on one of the temples, a slight blush of redness becomes visible, accompanied with stiffness rather than swelling of the *skin*; which has lost only its wonted suppleness, and acquired a shiny roseate hue. A tingling, burning sensation also, rather than pain, is experienced, and hence the popular name of this inflammation—St. Anthony's Fire. The redness of erysipelas assumes different tints; usually being more scarlet, rather than purple; but of whatever tint it may be, it disappears entirely on pressure, and returns immediately the finger is withdrawn—so free and persistent is the determination of blood. The tension also of the skin is readily perceived on passing the finger from the sound to the inflamed part. An abrupt margin defines this redness and this stiffness; both are circumscribed by an irregular line.

The inflammation, thus mapped out, spreads continuously: erysipelas is, par excellence, a "serpiginous" skin affection; and while it diverges, creeping like water spilt on an impervious surface, the skin becomes swollen, some serum is effused into the subcellular texture also, and *this* swelling is soft and diffused. Nature makes no adequate reparative effort to limit and circumscribe the serum with lymph. Serous effusion, therefore, proceeds, and the swelling increases—so much so as to close the eyelids, distend the cheeks, disfigure the features, and, at length, obliterate all traces of personal identification. "What great events from little causes spring:" that trifling red nose, and now this defaced visage. The turgid textures are tense and painful, although still a burning pain.

*Terminations.*—At this stage of the inflammation its course is sometimes arrested, the redness fades, the swelling subsides; and this termination by *resolution* occurs with or without shedding of the cuticle. In many instances, however, the issue is less speedy. Serous effusion, having

continued for a period varying from twelve to thirty-six hours, elevates the cuticle into vesicles, or larger blebs, exactly like those which follow a burn or scald. These semi-transparent and yellowish, or sometimes livid blisters, soon burst, and discharging their contents—serum, pure or bloody—subside into thin incrustations. When, in the course of a few days, these peel off, they disclose the subjacent skin either in a sound state or beset with superficial ulcerations. In some instances the true skin is less spared. It has a reddish-brown or livid hue, and even *gangrene* of the skin succeeds; announced by great tension, heat, and acute pain. But this issue of erysipelas is rare, and generally fatal.

Such are the origin, course, and terminations of *simple* erysipelas—an inflammation akin to erythema, and contrasting with the *phlegmonous* variety, in which the *skin* and *subcellular* texture are both the seat of inflammation; the latter tissue being more especially, but secondarily, engaged.

*Phlegmonous Erysipelas—and its Diagnostic characters.*—The roseate hue, if it should appear in the first instance, is soon exchanged for a brownish or livid tint which mottles the skin. Simultaneously, the subcellular texture is gorged with serum, and presents a considerable swelling, which, however, readily pits on pressure with the finger. This *œdematous* swelling, of considerable size, and this *purple* shade of colour exhibited by the skin, contrast with the characters of simple erysipelas as it first appears. The burning pain also is more severe, and perhaps accompanied with throbbing. Otherwise the simple and phlegmonous varieties have points of resemblance. In both, the redness presents a defined margin; in both, the inflammation extends itself continuously by creeping over the surface. But then again, in phlegmonous erysipelas, serous infiltration of the subcellular texture advances and deepens with alarming rapidity; and although itself diffused, the stuffed cushion of cellular tissue soon feels *bravny*. A few small vesicles only represent the overflow of serum under the cuticle; they do not reveal the perilous state of affairs beneath the skin.

*Terminations.*—Burrowing *suppuration* and rapid *sloughing* threaten; these dangers *not* being attended with increased tension, swelling, and pointing, as in phlegmonous inflammation; on the contrary, rather with diminished tension, subsidence, and flaccidity. Such is the experience of Lawrence,\* and of another original observer of this disease. At that period, writes Dupuytren,† when phlyctenæ have formed, and the cellular texture becomes thickened and indurated, the symptoms appear for two, three, or four days to be stationary; and an inexperienced surgeon is even led to hope for the resolution of the inflammation, while the danger is really urgent and suppuration already exists. This, then, is the critical period of phlegmonous erysipelas. If unchecked, the conclusion of its career is told in a few words. Very soon after this period of deceitful calm comes an outburst. A more livid hue overshadows the integuments; the skin melts away in patches, accompanied with a discharge of bloody sanious fluid, and the exposure of white sloughs of cellular tissue, portions of which bulge here and there through apertures in the integument. Sometimes this texture perishes extensively, but if partially spared, large sloughs of cellular tissue, resembling masses of soddened tow, are eventually detached; while the adjoining cellular texture is

\* Med.-Chir. Trans., vol. xiv.

† Clin. Chir., t. ii. p. 311.

drilled with small abscesses, or a profuse suppuration burrows wherever fluid can find its way—between muscles, and possibly into a neighbouring joint. Thus all parts around become involved in the ravages of phlegmonous erysipelas. In one fatal case, under Dupuytren's observation, the whole leg was laid bare of skin and cellular tissue, exposing the tibia and patella. After prolonged suppuration and sloughing, those textures which do escape—the muscles, fasciæ, tendons, and bones—are so agglutinated together as to seriously and permanently impair their uses in the animal economy.

It will be readily imagined that Erysipelas may spread from the scalp and face, to the neck, thence to the thorax, and occasionally extend as far as the extremities; or it may begin in some other part than the head and face—such as the leg, sometimes the trunk. In whatever part of the body Erysipelas first shows itself, its characters and course are similar; but while fading in that portion of the skin where it first appeared, it travels to the neighbouring skin. The various stages of this inflammation, therefore usually coexist in different parts of the skin; the portion last affected being red and swollen, another part vesicated, while others are undergoing desquamation.

It seems unnecessary to add a third variety of Erysipelas—the “œdematous” of some authors, for the phlegmonous variety is itself œdematous in one stage of its career. In both, a diffused infiltration of the subcutaneous cellular texture with serum is conspicuous, and the pitting of this œdema on pressure with the finger its most distinctive character.

*Phlegmonous inflammation* contrasts with phlegmonous erysipelas in certain particulars, and which determine their diagnosis—a question of much importance. Circumscribed and limited infiltration of the subcutaneous cellular texture with coagulating lymph, is the essential pathological condition peculiar to phlegmon. It is an inflammation of the *cellular texture primarily*, the skin being only secondarily involved; whereas phlegmonous erysipelas selects, first, the skin, and then involves the subcellular tissue. *Coagulating lymph*, rather than serum, is effused in phlegmon; the consequent swelling is therefore *circumscribed and limited*, instead of being diffused and wide-spreading; it is also *brawny in the first instance*, that of phlegmonous erysipelas only becomes so gradually; lastly, respecting the issue of these two species of inflammation—that of erysipelas is *prone* to slough, while that of phlegmon is liable only to this termination.

One word about a disputed matter: the liability of *mucous membranes*, as well as skin, to erysipelatous inflammation. This question is answered affirmatively by Stevenson, who gives a series of 21 cases,\* and subsequently by Arnott in an elaborate paper.† The former describes an affection of the throat, characterized by a red or purplish blush of the velum pendulum and uvula, with very little tumefaction, but considerable pain in swallowing. Excoriation of the inflamed surface frequently occurs, and superficial ulceration. This inflammation is *preceded* by febrile symptoms, even in mild cases, and may occur before or after the skin affection; it may, indeed, constitute the whole attack of erysipelas, without that of the skin supervening. Other men of observation—Lawrence, for instance, with whom I am inclined to concur—do not acknow-

\* Cases illustrating the contagious nature of erysipelas, and its connexion with a severe affection of the throat. *Edin. Med.-Chir. Trans.*, vol. ii., 1826.

† *Lond. Med. and Physical Journ.*, vol. lvii., 1827.

ledge erysipelatous inflammation of any mucous membrane. But this is still an open question.

*Fever.*—Erysipelas is not announced by any peculiar functional disturbances. They constitute a fever, and of the typhoid type. But, as Gregory observes, "there is nothing characteristic of approaching erysipelas, as contra-distinguished from any other kind of eruptive ailment." "The pulse is peculiarly quick and sharp at the onset of this fever." Erysipelas of the face is said to be *preceded* and accompanied by a fever, of which "a peculiar affection of the sensorium" is the prominent symptom; and the initiatory fever of idiopathic erysipelas, in every case, is said to be accompanied by "inflammation of the fauces." Both these statements are confirmed by Arnott, and the latter symptom—sore throat—is associated, in Sir Thomas Watson's experience, with erysipelas of the head and face.

*Blood-pathology.*—Erysipelas has been thus examined, yet with little result. The blood is rich in fibrin, and poor in globules; but these alterations, together with others that occur, are common to all the phlegmasiæ. They are not peculiar to erysipelas, and therefore not characteristic. The circumstances of therapeutic treatment, age, &c., seriously affect the results of any analysis obtained in respect of this, as well as of all blood-diseases.

*Blood-origin, and Infection.*—Erysipelas may be caused by infection—*i.e.*, it may be produced by inhalation from a person having the disease. But this mode of production is observed only in some cases. Of such, the following, from original authorities on this subject, are noteworthy. Certain cases reported by Dr. Wells\* are much to the point. An elderly man was attacked with erysipelas of the face, and died in about a week from the time when Dr. Wells first saw him—*viz.*, on the 8th of August. On the 19th of the following month an elderly woman, landlady of the house in which the old man had been a lodger, came under the care of Dr. Wells, also with erysipelas of the face. On inquiry it was found that the old man's wife had been seized with erysipelas a few days after his decease, and had died in about a week. Another old woman who had nursed the landlady was also attacked with this disease and died. Lastly, a young man, nephew of the old man, was seized, shortly after visiting his uncle, and died in a few days. In this last case the probability of infection having been the cause of erysipelas is obvious, and with some probability the same mode of propagation may be inferred respecting the whole series of cases. For the report further states, that the landlady had been several times with the old man and his wife during their sickness, and that after their death she had removed some furniture from the room they had occupied to her own apartment. Cases of like import occurred in the practice of Dr. Wells's contemporaries—Mr. Whitfield, apothecary for very many years to St. Thomas's Hospital, Pitcairn, and Baillie, who made similar observations in St. George's Hospital during the years 1795-96. Many years afterwards, to show the growing impression in favour of this doctrine, I might refer to cases of infectious erysipelas, recorded severally by Dickson,† Blackett,‡ and Stevenson.§ Then Mr. Arnott|| took up the inquiry. He collected what had been

\* Trans. of a Society for the Improvement of Med. and Chir. Knowledge, 1800, vol. ii. p. 214.

† Med.-Chir. Journ., April, 1819, p. 615.

|| London Med. and Physical Journ., 1827, vol. lvii.

done by others, and added the results of his own observations. "In one family, the mother was first affected with inflammation of the pharynx, terminating in mortification. On her death the husband was attacked with inflammation of the throat and erysipelas of the face. As he recovered, the daughter was similarly seized with inflammation of the pharynx and severe erysipelas." Five years prior to this Paper, although published subsequently, a series of observations yet more convincing, if possible, were made by Dr. Gibson.\* For example, the infant son of a gentleman was seized with erysipelas on one foot. Afterwards, the mother became affected with erysipelas of the face and scalp. Then the nurse, who suckled the child, was attacked with symptoms of pneumonia. She was removed to her father's house, four miles off. He, who some days before her arrival had received a wound of the scalp, was now seized with erysipelas of the face and scalp, and died. Soon afterwards, a sister, living in the same cottage, had fever with sore throat, from which she slowly recovered. Two children, in the same house, were cut off with what appeared to be croup.

Taking a fair estimate of all these cases, it will be obvious that those are most decisive where the persons who became affected reside at some distance from the house in which erysipelas first manifested itself. Persons living together might possibly be subject to some endemic source of disease—as bad drainage, or insufficient ventilation.

But if the fact of persons acquiring erysipelas, after associating with those who have this disease, is in favour of its propagation by infection; so also, when the source of contamination is removed, the disease should cease to spread. Of this the following is an illustration:—The wards of the Dublin Fever and Dysentery Hospital were large and extremely well ventilated. "On paying my daily visit," writes Dr. Brereton,† "I observed one of the patients, who had been admitted with fever some days previously, to be formidably attacked with erysipelas. On the following day I found the patient in the next bed seized with it. On the third day, two patients in the adjoining beds were similarly attacked. I then," continues Dr. Brereton, "became seriously of opinion that the disease was contagious, but resolved not to have those already affected removed until I had tried the result of another day. On the following morning, I found three more in like manner labouring under the disease; and what made it more remarkable, they were all similarly attacked in the head and face. I had them immediately put into another ward, where there were no patients; they all recovered, and no more erysipelas afterwards appeared." In this series seven patients were attacked successively, but here the supposed cause being removed, its effect ceased.

Respecting, then, the propagation of erysipelas by infection, we have the *double* test of causation fulfilled; the presence of erysipelas is at once followed by this disease in persons associating therewith, and, being withdrawn, the disease at once ceases to multiply.

It has been affirmed by some men of observation that this law holds good *only* of erysipelas affecting the face and scalp. Arnott and Watson are of this opinion; but, restricting, as they do, their definition of this disease to its manifestation on the head and face, the law of infectious propagation becomes absolute. Other authorities, however—and the

\* Edin. Med.-Chir. Trans., vol. iii., 1829.

† Dub. Journ. of Medical Science, vol. vi. p. 176.

majority—who do not take this localized view of erysipelas, are inclined to acknowledge its propagation by infection. My own observation has not been sufficiently directed to this matter to warrant me in offering a decisive opinion; further than this, I can throw into the scale my testimony as to the infectious character of facial erysipelas, and probably of every *idiopathic* manifestation of the disease on any part of the body.

Are *fomites* capable of transmitting this disease? Yes, certainly. Among the earlier writers, Wells observed that a certain patient caught erysipelas in consequence of being laid in the unchanged bed of one who died of it. Similar instances have occurred in the experience of most practitioners, unless due precautions were taken to prevent this risk of infection. But the wards of an hospital may themselves become contaminated, and communicate the disease on a larger scale. By Gibson's Report, already quoted, we learn that a woman, with erysipelas of the hand, having been admitted into the Montrose Infirmary, and the patients in either adjoining bed having become affected, the whole ward was then cleared out, cleansed, whitewashed and fumigated. "Yet when they were again placed in that ward the disease reappeared," and it became necessary to remove all the patients from this little infirmary, and to take every precaution ere the infection was eradicated. The contaminating power of fomites, in the shape of furniture, floors, &c., is evinced by the fact that dry rubbing instead of washing the floors of an hospital, or the decks of a ship, is the surest safeguard against this source of infection. But fomites of all kinds retain most tenaciously the poison of erysipelas; and, indeed, Gregory is of opinion that this poison is banished with more difficulty than any other known miasm.

The *period of latency or incubation*—varying in each kind of infectious disease—in erysipelas, extends from two to fourteen days; and when developed, the *infecting area* is twenty to thirty feet.

*External causes.*—Erysipelas acknowledges, apparently, a *traumatic origin*, in some instances. Hence, therefore, all kinds of wounds, injuries, surgical operations, and irritants—such as blisters, caustics, &c.—are accredited causes of this species of inflammation. Besides mechanical and chemical irritants, heat and cold may be accorded their share of importance.

*Predisposing causes.*—Any external cause may be reinforced, at least, by conditions within the body; resulting mostly from previous habits of *intemperance*, previous hardships, or both, perhaps also from mental depression—circumstances which have depraved the blood and enfeebled its circulation. But the disease is also most prevalent in spring and autumn, or at least when hot and cold wet weather alternate; and if period of the year has some predisposing influence, so also has the period of life, they being most liable who are *old* in years, or old for their years.

Apart from predisposing causes, erysipelas, probably, would not arise; with their concurrence the scratch of a pin only may be apparently the traumatic origin of this disease. Yet even in such cases its infectious character becomes developed. In one instance, noticed by Lawrence,\* erysipelas of the head and face, consequent on the insertion of a seton in the neck, was the only presumptive cause of this affection in two other persons. Travers,† indeed, goes so far as to affirm that he has repeatedly seen the "*idiopathic*" arising from the "*traumatic*," or this from the former, and either from its own source.

\* Op. cit.      † Constitutional Irritation. Further Inquiry, 1835, p. 149.

Lastly, the possibility of erysipelas arising *spontaneously*—that is to say, in an individual without any assignable external cause, and therefore without infection—is, I think, indisputable.

The *recurrence* of this disease in the same individual is possible. I can speak from my own personal experience, having had it *four* times severely, in my head and face, when from nine to thirteen years of age. I was then a pupil at the King's College School, and although many years have elapsed, I well remember the flaming pain, and that my face was like a distended bladder. I just mention these particulars to verify so early a reminiscence in evidence of an important fact, that susceptibility to *true* erysipelas—*i.e.*, affecting the head and face—is not exhausted by one attack. Unlike most eruptive fevers, the blood does not lose its capability of undergoing this infection, again and again.

*Treatment.*—*Preventive* measures must have reference to the causes of this disease. Its propagation by infection suggests the prompt isolation of any person having erysipelas—as the source of infection, free ventilation of the apartment, and the separate use of any bedding or other infected article, which might act as a *fomes* in carrying the disease to other patients. Dry-scrubbing instead of washing the floor of the bedroom or ward, has already been alluded to as a safeguard; evaporations favouring, apparently, the dissemination of the infected atmosphere. Cleanliness with regard to the dressings used for other patients, and on the part of the nurses, is an obvious injunction. With all these precautions, a nurse or the practitioner himself may yet be the medium of communicating the disease. Disinfectants, such as chlorine vapour, or chlorinated solutions, permanganate of potash, and carbolic acid lotions, have more or less influence in purifying a contaminated atmosphere, or in guarding the wounds of patients who may be exposed to its operation.

These preventive measures are less urgent with reference to erysipelas of traumatic origin.

Predisposing causes, pertaining as they do mostly to the previous health of the individual, scarcely admit of prevention. They suggest, however, the greater protection of persons thus liable to infection. Such are persons whose blood has been depraved, and circulation enfeebled, by previous habits of intemperance, and by the wear and tear of a laborious, anxious life. Albuminuria is peculiarly inviting to erysipelas. Diabetic patients also are said to be liable.

*Remedial* treatment—so-called—is a misnomer; for, like all infectious diseases, erysipelas runs a certain natural course, and the only power of art is to avert any unfavourable tendency. It is probable that a blood-poison is undergoing elimination from the system, through the great secreting surfaces—the skin, thus inducing the inflammation, and the mucous membranes. Consequently, the bowels having been evacuated by a mercurial and rhubarb or colocynth pill, a saline aperient, diuretic and diaphoretic mixture, may then be given with advantage for some days. Thus, the sulphate of magnesia, with nitrate of potash and small doses of tartarized antimony, seem to promote elimination. The acetate or carbonate of ammonia, in camphor mixture, will be more specially diaphoretic. Bicarbonate of potash, in large doses, say half a drachm, has sometimes appeared to me, to fulfil a special purpose, that of neutralizing the blood-poison, whatever it be. Erysipelas is, I think, thus allied to rheumatism or rheumatic gout, to erythema and urticaria; in all of which diseases potash has some peculiar remedial influence. And in harmony

with their therapeutic affinity, I have observed clinically, that the same individuals are not unfrequently subject to each of these diseases. A dusky yellow hue of the skin, and slight yellowness of the conjunctiva, with perhaps nausea and oppression of the stomach are often present in erysipelas. This condition, verging on jaundice, is best overcome by the repeated administration of calomel or blue pill, to restore the secretion of bile. A blister over the region of the liver, is also, I believe, recommended by Mr. Syme. These measures are apparently more efficacious than the ipecacuanha emetic usually ordered to empty the *stomach*.

The saline plan of treatment will, generally, prove sufficiently depletory—as well as excretory—without having recourse to blood-letting, to however small an amount. Debility, and the increasingly typhoid character of the fever, from the commencement of the disease, soon indicate the necessity for the substitution of a stimulant and tonic treatment. Carbonate of ammonia, in five or ten-grain doses, with disulphate of quina, in similar or even larger doses, may be given every four hours. Tincture of the sequichloride of iron, from ten to twenty minims every two hours, is highly extolled by Dr. Balfour—as a certain and unfailing remedy, whether the erysipelas be infantile or adult, idiopathic or traumatic.

The *diet* must correspond to this medicinal treatment. Wine should be given, tolerably freely, in all cases, and even from the very beginning. Brandy and egg beat up together, form a convenient and agreeable mixture, at once stimulating and nourishing. Beef-tea and the other preparations of nutritious and easily assimilated food, represent the general character of our dietetic resources.

Now, the degree to which this depletory, or stimulant and tonic, plan of treatment should be pushed, will vary with the symptoms, as they are more those of inflammatory or of typhoid fever. As the pulse becomes feeble and rapid, the tongue coated with a brown fur, and increasing debility supervenes; so must the one treatment be exchanged for the other.

It is thus that the *phlegmonous* variety of erysipelas may, in the first instance, require *more* active depletory measures—purgative, diaphoretic, and diuretic salines, with antimony, in doses to touch the pulse, and the occasional use of blue-pill or calomel, in slightly cholagogue doses; but these measures must soon be exchanged for a yet *more* free administration of quina with carbonate of ammonia, and a more supporting diet also, than in simple erysipelas.

And again, erysipelas of *traumatic* origin may need yet further support, in proportion to the severity of the injury conjoined with the erysipelas.

*Local Treatment.*—Any *repressive* application would be obnoxious; not only as tending to divert the natural course of the disease, in the elimination of the blood-poison, but as possibly repelling the inflammation to some other part, its migration or metastasis being perilous and prolonging the disease. In both these respects, the cutaneous inflammation of erysipelas is analogous to an *attack* of gout.

Warm fomentations by spongio-piline or flannel steeped in a hot decoction of poppy-heads or chamomile flowers, and continuously applied, will hasten the termination of the inflammation by resolution. These epithems are also more soothing to the patient than dredging the part with flour or magnesia; a dirty, encrusting, and irritating application

formerly in vogue, and still recommended by some authorities. Nor can much be said in favour of a strong solution of nitrate of silver, as an application to the inflamed surface; which, if it fail by its astringent action to induce resolution, may, by over-stimulation, provoke sloughing. A circumferential line drawn with the nitrate of silver, strongly pencilled, was recommended by the late Dr. A. T. Thomson, for the purpose of setting up a sort of incompatible inflammation, and thus arresting the progress of the erysipelas. But this boundary rarely, if ever, proves a barrier; such at least is the result of general experience; and I now never have recourse to the nitrate of silver in either of these ways.

*Phlegmonous* erysipelas presents nothing peculiar, otherwise than as pertaining to the subcutaneous cellular texture, which, with the skin, is invariably although secondarily involved. *Free incisions*, and at an *early period*, therefore, fulfil a twofold purpose. By relieving tension, they may be preservative of the skin, and perhaps of the subcellular texture; both of which are so apt to slough extensively. Moreover, pain is thus relieved, and the inflammation itself moderated by a discharge of blood with the serum effused. It is, indeed, remarkable to notice how the skin speedily loses its purple hue, and becomes almost blanched, as the engorged vessels bleed freely; the patient acknowledging a proportionate mitigation of the pain previously endured. Incisions also facilitate the discharge of pus and sloughs, which to some extent are inevitable. The preventive and curative efficacy of this treatment is now generally admitted; but the number, length, and depth of the incisions, are particulars about which differences of opinion exist. Some surgeons prefer one long incision, a practice, however, fraught with probably more danger from shock and hæmorrhage, while it is certainly less effectual for the relief of tension than incisions in different parts. A few cuts—three or four, and of as many inches in length, will be sufficient in most cases. In no case, need they be carried deeper than into the subcutaneous slough, which is easily recognised by its ash-grey colour. The treatment subsequently is similar to that of any other suppurating and sloughing wound.

## CHAPTER IX.

### PYÆMIA, OR PURULENT INFECTION.

THE term Pyæmia literally signifies Pus in the Blood (πύον pus, αἷμα blood), or purulent infection of the blood; a systemic condition arising most commonly, or which was first observed, in connexion with the local condition known as suppurative phlebitis; and which is, generally, soon followed by the formation of secondary abscesses, or at least by collections of matter—secondary to the primary disease, and which are distributed in various remote organs and parts of the body. But, in addition to this dependent series of affections, Pyæmia has more recently acquired a more comprehensive, and less definite, pathological significance; as representing, also, the systemic infection which arises from the introduction into the blood of *animal* or *septic* matter.

Two, or more, kinds of systemic infection would thus be associated; allied in their nature, probably. It, however, seems desirable, for the

sake of accuracy and clearness of description, to dissociate them; and first, to restrict the term Pyæmia to its originally definite etymological meaning—purulent infection, and as arising, for example, from an ordinary suppurating wound; and then, give it its enlarged signification, as in connexion with poisoned wounds—for example, dissection-wound.

**PYÆMIA.**—*Symptoms.*—A wound suddenly ceases to secrete and discharge pus—becoming drier or glazed; this morbid change is followed by concussive *rigors*, more or less violent, and in duration lasting for a few moments or for some minutes; then prostration; the face looks haggard, vacant, and alarmed, as if the individual were conscious of some vital injury—the nervo-muscular system responding by a prolonged shudder. This is not necessarily accompanied with a sensation of cold. Rapid sighing completes the picture of prostration. At length the heart arouses, and the pulse rises, perhaps to 150 in a minute, beating feebly and irregularly; soon a scorching heat of skin is experienced; flooding perspiration succeeds. The paroxysm is over. Similar paroxysms may recur at periods varying from twelve to thirty-six hours;\* or at about the same hour for three or four days; or at irregular intervals.† Probably, in most cases, rigors occur once for all, then *absolute* prostration, from which no perceptible reaction ensues. Whether prostration be continued, or relieved by fits of reaction, other significant symptoms supervene. The skin becomes overcast with a dirty yellow tinge, and the abdomen tympanitic. All the secretions show signs of a blood-poison being ineffectually eliminated. Rank perspiration, often profuse, ammoniacal urine, and a putrid diarrhœa, alike compete incessantly to evacuate it; but these drains only help to complete the exhaustion. The breath has been noticed by Bérard and Mr. Gamgee to have a very peculiar odour, compared by the latter to that of sweetish liver or of new hay. In one well-marked case of pyæmia this odour was absent; and it was present without pyæmia in two other cases—one of prostatic abscess, the other, extravasation of urine after lithotripsy. The diagnostic value of this symptom is therefore equivocal. Eventually the tongue and perhaps the lips are dry and brown, or black. Sometimes a leaden hue overspreads the face (Gamgee). No time is allowed for progressive emaciation, as with hectic, prostration is so overwhelming:

“the life of all his blood  
Is touched corruptibly; and the pure brain  
(Which some suppose the soul's frail dwelling-house)  
Doth, by the idle comments that it makes,  
Foretell the ending of mortality.”

Pyæmia is not always fatal. Sédillot‡ and Vidal§ have recorded cases of recovery. Nélaton|| dissents, and affirms that death is inevitable. It takes place usually about the tenth day; sometimes earlier, as the third day, or, much later—six or seven weeks.

*Secondary Abscesses.*—Post-mortem examination reveals numerous abscesses in one or more organs and textures of the body; and they are not inaptly termed *secondary*, because subsequent to an abscess, or at least to suppuration, in some other part. Secondary abscesses most

\* On Pyæmia, J. S. Gamgee, 1853.

‡ De l'Infection Purulente, ou Pyémie, 1849.

§ Traité de Pathologie.

|| Élémens de Pathologie Chirurgicale, p. 167.

frequently occur in the lungs and liver. Their general characters are these:—In several portions of the organ affected, black blood has accumulated; such portions are indurated, but brittle and easily break down under slight pressure with the finger;—the texture is congested and disintegrated. Some of these disintegrated portions present a yellow spot of pus in the centre of the black mass; in other parts pus has altogether supplanted the blood and disintegrated textures; and these *pus-deposits* are tolerably circumscribed; in fact, abscesses are formed, each surrounded with a dark margin of congested texture. Mr. Lee\* states that the central spot of each affected portion at first consists of lymph, which gradually extends towards the circumference. If the disease continue, these spots suppurate, the affected portions having previously softened and disintegrated in the same order in which they were primarily solidified. Secondary abscesses are usually of a small size, in the viscera varying from a pin's head to a walnut, very numerous, and of rapid formation, a few days sufficing for their development in many organs. Although most commonly found in the lungs and liver, other organs and tissues are not exempt. They occur elsewhere—approaching the following order of frequency—in the spleen, brain, kidneys, heart, skin, mucous membranes, within serous and synovial cavities, in the muscles and cellular tissue, and in the eye; in the prostate (Gamgee).

The *diagnosis* from primary abscess is twofold. It will be observed, that the chosen seat of an ordinary or primary abscess—the cellular texture—is not the usual habitation of secondary abscesses; and usually there are no local symptoms—no pain, or functional derangement, although certain parts—as the lung, pleura, peritoneum, and intestinal canal—will not tolerate secondary abscesses without some local symptoms of disaffection. It may also come to pass, that death ensues from coma, asphyxia, or from necræmia as the result of further blood-poisoning accruing from the non-elimination of various excrementitious matters.

The blood itself has undergone serious changes of chemical composition, probably; of physical properties and vital endowments, certainly. It has less plastic power, coagulates imperfectly and less readily. Hence, the more fluid blood is apt to transude, minute hæmorrhages take place in various textures, and the gastro-intestinal mucous membrane is stained with a reddish tint.

*Pathology of Pyæmia.*—Having stated the leading facts relative to pyæmia as at present known, and its local consequences; to what theory or explanation do they point? I have just alluded to certain changes which pyæmic blood is found to have undergone after death. Now, the circumstances under which pyæmia arises lead to the *inference* that during life *pus* itself, as *bonâ fide* pus, has entered the circulation, either by suppurative inflammation of the veins—occasionally of the lymphatics, rarely of the arteries; or by absorption through the veins, aided by the lymphatics, laid open and exposed by mechanical injury, as by wounds, or rapid sloughing of the suppurating part: and that the pus thus produced within vessels, or introduced from without, possibly circulates with the blood, inducing secondary deposits. Each clause of this sentence must be submitted to the test of clinical observation.

(1) *Suppurative Phlebitis.*—Without doubt, *suppurative* inflammation

\* Op. cit., p. 52.

of a vein induces pyæmia, and thence secondary abscesses. Hunter\* originally observed, that "in all cases where inflammation of veins runs high, or extends itself considerably, it is to be expected that the whole system will be affected. For the most part, the same kind of affection takes place which arises from other inflammations, with this exception, that where no adhesions of the sides of the vein are formed, or where such adhesions are incomplete, pus, passing into the circulation, may add to the general disorder, and even render it fatal."

All subsequent observers have confirmed Hunter's observation as to the fact that suppurative phlebitis is frequently followed by pyæmia; some, moreover, have adopted his theory, that pus entering the circulation is the immediate cause, and have extended this view to interpret the formation of secondary abscesses; while no one, in my opinion, has ever disproved it. In 1815 Hodgson† supported the Hunterian theory of pyæmia; and although Travers‡ alleged that suppurative phlebitis was comparatively harmless, and the adhesive fatal; yet the influence of his opinion was soon reversed, the potency of pus-forming phlebitis re-acknowledged, and Hunter's theory re-adopted. Carmichael,§ contributed his observations and his concurrence with this interpretation of pyæmia. Abernethy|| followed, rather as a disciple than as an original observer, in this department of Pathology. Then the French school instituted investigations to discover the immediate cause of pyæmia from suppurative phlebitis. Their results were, with scarcely an exception, in favour of Hunter's suggestion. Bouillaud¶ contributed his clinical researches, ascribing the constitutional consequence of phlebitis to pus in the blood. Cruveilhier\*\* likewise came to the conclusion, that pus is transmitted from the veins in which it is formed; and his observations of the stages of suppurative phlebitis tend to establish two facts. Firstly, when pus produced within a vein is excluded from the general circulation, as by a barrier of coagulated blood, or by adhesion and obliteration of the vein, no symptoms of pyæmia ensue; secondly, when the obstruction is removed, the symptoms of pyæmia immediately commence. The unavoidable inference is, that pus is carried from within the suppurating vein into the general circulation.

It would appear that pus is first formed, not between the vein and the clot, but in the very centre of the coagulum, which soon blocks up an inflamed vein. The symptoms of pyæmia do not arise then; but the proportion of coagulum diminishes, while that of the pus increases, and this may take place here and there in the course of the vein, as the inflammation is more or less advanced, thus presenting adhesive, alternating with suppurative, phlebitis. Usually, adhesive phlebitis limits and circumscribes the suppuration; and then, also, the general mass of blood

remains uncontaminated.\* Pyæmia does not arise under these circumstances. As phlebitis advances, the distended vein becomes knotty at the various portions where pus has accumulated; eventually the vein bursts, pus is deposited in the surrounding cellular tissue, and abscesses are formed. Pending this issue, when the dyke made by the *clots* is broken, and removed by absorption, typhoid symptoms immediately commence, announced by violent rigors, soon succeeded by death. Frequently a patient, who overnight exhibited no constitutional symptoms of pyæmia, is found next morning in a dying state, and perhaps almost the moment when pus entered the circulation can be noted.

Duly considering these facts, it is scarcely necessary to bring forward the corroborative testimony of other observers. Dance† and Blandin,‡ both attributed pyæmia to the transmission of pus from suppurating veins. Mr. Arnott,§ also was led by his observations of pyæmia in seventeen cases, cases of fatal phlebitis, to conclude that the entrance of pus into the circulation is its principal cause, “a similar influence being, perhaps, also possessed by any inflammatory secretion from the vein.” Andral|| promulgated this doctrine, and Carswell¶ likewise; alleging that with all the facts before us—namely, the existence of suppurative inflammation, the presence of a greater or less quantity of pus in the veins, evidence that the pus so situated is the product of inflammation of these veins, and of this morbid product being carried into the blood by the collateral venous circulation—it appears that a satisfactory explanation may be given of the formation of those anomalous collections of pus which take place in remote parts of the body. Dupuytren, Bérard, Vidal\*\* (de Cassis), and Sédillot†† concur in the doctrine of pus-transmission; the latter observer maintaining that pus can actually be seen in the blood when examined under the microscope. Remembering the great difficulty of clearly distinguishing pus-cells from the pale corpuscles of blood, I cannot accord much weight to this argument. Certain observers have been content to record the important fact that suppurative phlebitis very frequently induces the constitutional disorder known as “pyæmia,” without specifying its immediate cause. Ribes‡‡ does not assign the transmission of pus nor any other explanation of this question; neither does Breschet§§ nor Guthrie.|||

On the other hand, respecting suppurative phlebitis as a source of pyæmia; it is alleged by some observers, that the living membrane of veins is indisposed to inflame and is perhaps incapable of secreting pus. The systemic infection is attributed by Virchow, and other pathologists, to the disintegration and decomposition of *fibrin*, in the shape of coagulum within the veins, and which enters the circulation.

Others have denied the possibility of pus entering the circulation under the ordinary circumstances of suppurative phlebitis. Tessier\* alleges that at *all* stages of venous inflammation the pus is *enclosed* in the cavity of the vein by clots or false membranes, and that at no period of the anatomico-pathological existence of phlebitis, is its entrance into the blood possible. Mr. Lee appeals to the results of experiments on blood out of the body. In the preface to his Jacksonian Prize Essay,† he urges that “the simple experiment of mixing some pus with healthy, recently drawn blood, will at once show that such a combination cannot circulate in the living body. It will be found that the blood *coagulates* round the globules of pus, and forms a solid mass which will adhere to the first surface with which it comes in contact; and it will be evident that it is not till the coagulum thus formed is broken up or dissolved that its elements can circulate with the blood.” But, Mr. Lee’s inference from his “simple experiment” *assumes* that that which is true of blood mixed with pus *out* of the body, is also true of blood *circulating* with pus *in* the *living* body. The inference drawn breaks down, because the circumstances of the two cases are so essentially different. This, as Hunter said, is “putting living and dead animal matter upon the same footing, which is a contradiction in itself.” The inference which Mr. Lee has drawn from his experiments is therefore without appropriate foundation.

(2) *Suppurative Lymphatitis*.—The fair inference from all the facts—pathological and clinical—which I have adduced is, that pus *enters* the general circulation during the course of suppurative phlebitis. By analogy, pyæmia may be expected to arise also from suppurative inflammation of the *lymphatics*. Similar symptoms to those of pyæmia arise occasionally after slight pricks and wounds received in dissection, and similar consequences ensue. How far this constitutional disorder, and these consequences, are due to the *animal* or *septic* matter inoculated, is uncertain. The very worst constitutional symptoms may follow the slightest prick where the quantity of animal matter introduced must have been minute; and equally bad symptoms may follow a bleeding wound where the animal matter has been washed away: while the most fatal cases are generally those of wounds received in the post-mortem examination of uterine phlebitis with suppuration, and pus-forming peritonitis; and lastly, the constitutional symptoms are in the *ratio* of the local inflammation and suppuration.

For these reasons I am inclined to regard the constitutional disorder arising from *dissection wounds*, when *accompanied* with inflammation of the lymphatics, as pyæmia, from pus having thus entered the general circulation. And as I have said, the symptoms and the consequences are similar. Severe *rigors* announce the transmission of pus; this primary symptom occurring, not at the time of the prick or cut, but after the lymphatics have become inflamed. Prostration, extreme, with a countenance expressing dread apprehension, show that the poison continues in operation. Partial reaction may succeed, but eventually the pulse becomes very weak and very rapid. A dusky yellow tinge sometimes overshadows the skin, and the tongue is coated with a brown fur. Fætid perspiration and alvine evacuations may apparently eliminate the poison and restore health, or oppressive wandering delirium betoken approaching

\* Archives Générales de Médecine, 1839, iii. ; et nouvelle sér., t. iv. p. 86.

† On the Origin of Inflammation of the Veins, and on the Causes, Consequences, and Treatment of Purulent Deposits, 1850.

death. Such are the chief general symptoms. Local and significant ones have also been noticed, and accurately described, by Macartney,\* Colles, and others. As the disease progresses, inflammatory tumours arise successively in parts of the body remote from the original wound, and of a character which augments the constitutional sympathy, for they are not bounded by the effusion of lymph. According to Macartney, pus is rarely formed, and when these tumours have been cut into on the supposition of their being abscesses, they have been usually found to contain only a bloody serum. Mr. S. Cooper states† that, in a large proportion of the cases which he attended, purulent matter was formed and discharged. A common situation for such abscess is under the great pectoral muscle. Local signs of inflammation are frequently present. Colles‡ dwells on the significance of a peach-blossom redness, unlike the hue of erysipelas, and acute pain is sometimes felt in the part. Thus these secondary purulent collections contrast somewhat with those which proceed from suppurative phlebitis.

(3) *Arteritis* rarely advances to suppuration, and more rarely are there any constitutional symptoms of pyæmia. But now and then, utter prostration, with an incredibly rapid pulse, suggest this inference, and the oppressive delirium of pyæmia speedily closes the scene. Post-mortem examination is wanting to complete our knowledge of these cases.

(4) Suppurative phlebitis, suppurative inflammation of the lymphatics, and possibly, suppurative arteritis, are not the only sources of pyæmia; the immediate cause being the *direct* transmission of pus from the vessels in which it is formed into the general circulation. Precisely the same constitutional disorder frequently follows the *absorption* of pus from suppurating surfaces, as wounds and sores. Velpeau, Maréchal, Rochoux, and others have attributed pyæmia solely to absorption, and in such cases.

What are the particular circumstances which allow the absorption of pus from a suppurating surface, so as to induce pyæmia? It is well known that pus may be absorbed from an abscess without pyæmia ensuing; and long since Cruveilhier§ pointed out the important distinction between the absorption of pus when *prepared* for absorption, and pus in the condition of pus, at once entering the circulation. In the former case, no constitutional disturbance follows; in the latter, pyæmia. To allow of the absorption of pus in an *unaltered* condition, the *absorbing vessels* must have been laid *open*; the veins, lymphatics, or both, must have undergone solution of continuity; and this, either by a wound without subsequent repair, or by rapid sloughing, without time for closure of the vessels by the adhesive process. They therefore remain open during suppuration, and their mouths—so to speak—being in immediate contact with pus, allow of its admission, and transmission.

This mode of purulent infection accords with Mr. Liston's observation,|| that, "when from any cause the extremity of a large vein in a wound is not closed—when it is not plugged up by plastic matter, pus seems to enter it readily, and by mixing with the circulating fluid, causes dreadful mischief. Great constitutional disturbance accompanies the purulent deposits which follow in the solid viscera and in the joints." In

other cases these results are preceded by rapid sloughing. A wound suddenly loses all power of healing by adhesion, and any adhesions that may have formed give way, the granulations become pale and flabby, and true pus is no longer discharged; the surface acquires a mottled brown colour, and by this time symptoms of pyæmia have commenced. Burns, attended with extensive suppuration, are not unfrequently followed by pyæmia; and certain specific diseases, as glanders, in like manner, threaten purulent affection by absorption. Occasionally, suppurative phlebitis advances so far as to allow of absorption through a vein having burst, and opened into an abscess. In one case, the femoral, popliteal, posterior tibial, and peroneal veins, communicated with abscesses (Cruveilhier). In another case, the internal jugular vein opened into a neighbouring abscess (Travers). More frequently, inflammation of the lymphatics is accompanied with extensively diffused suppuration, and induces pyæmia, partly by the absorption of pus.

*Formation of Secondary Abscesses.*—The mode of production of secondary abscesses, in various and remote organs and parts of the body, in consequence of purulent infection of the blood, is doubtful. It may be, by the arrest, and actual deposition of pus in the capillaries of the parts affected, conveyed there through the circulation—the theory originally entertained; or, that the arrest of pus, or of disintegrated fibrin, in these vessels, induces suppurative inflammation—phlebitis, of the smaller veins. This latter mode of formation was suggested by Cruveilhier, and seems to be the more probable explanation of secondary abscesses.

*EXCITING CAUSES, AND THEIR OPERATION.*—*Injuries and surgical operations* attended with much suppuration, are well known to threaten pyæmia; and they do so *partly*, perhaps, by absorption of pus, and *partly*, by suppurative inflammation of the disorganized veins. Compound fractures may thus occasion purulent infection; and injuries of the head probably operate chiefly by suppurative inflammation of the veins of the diploe. Dance first suggested this explanation; Cruveilhier gave the anatomical proof by dissection. Indeed, the latter observer affirms that phlebitis of bones is one of the most frequent causes of visceral abscesses, from wounds and surgical operations implicating the bones. The mere removal of a piece of necrosed bone is sometimes followed by pyæmia; but whenever destruction of the osseous texture, accompanied with suppuration, is followed by pyæmia, absorption of pus probably has been partly the cause, its absorption being determined by the anatomical condition of the veins, which are kept open by the bony channels through which they pass. Amputations of the limbs, of the breast, lithotomy, and the operation for fistula in ano, likewise threaten pyæmia, when suppuration is abundant. Absorption and suppurative phlebitis may co-operate in these cases to infect the blood with pus. They assuredly co-operate in pyæmia following venesection. The vein is punctured, and the aperture absorbs pus, subsequently diffused around the vein; while the vein itself, having suppurated, transmits pus into the general circulation. Probably, suppurative inflammation of the lymphatics contributes to pyæmia, in some cases where and when absorption of pus may have taken place. A faint blush in the course of the lymphatics frequently supervenes on the sudden cessation of a purulent discharge; forthwith pyæmic symptoms commence; eventually the lymphatic vessels appear as red lines ramifying from the sore, becoming harder and more painful—more inflamed, in fact, as pyæmia advances.

*Treatment.*—*Preventive* measures will consist in the rigorous observance of hygienic precautions, especially with regard to cleanliness in dressing a wound, and free ventilation; and in the preparation of the Patient for any operation (p. 11). Pyæmia is scarcely amenable to any *remedial* measures. Stimulants and tonics, with as much nutritious and readily assimilated food, as can be taken, constitute the only plan of treatment for probably sustaining the patient through the dread exhaustion which must be undergone, even when recovery ensues. Thus, wine, brandy, or as brandy and egg-mixture, strong beef tea, ammonia and quinine—in large doses, as four or five grains, may be administered repeatedly, every three or four hours. Opium has a marked beneficial influence in controlling the rapidity of the pulse, and the general irritability associated with prostration. Cleanliness in the dressing of any wound, and free ventilation, must also be observed. Secondary abscesses, when tense, and in any superficial or accessible part, may be opened; and by a valvular incision, as in the treatment of a chronic abscess, so as not to admit air to the readily decomposing purulent collection.

## CHAPTER X.

### HOSPITAL GANGRENE.

HOSPITAL GANGRENE is fortunately known to but few surgeons in civil practice now living; and we must refer to those of the past for information. The shortcomings of personal observation, are however amply compensated by the testimony of many witnesses on record; for a disease so formidable has ever been watched with deep interest whenever it occurred. From *original* sources of information, therefore, we are enabled to identify this disease, while its etiology suggests appropriate preventive measures. Hospital gangrene has received various other names; not because of any doubt respecting its pathological nature, but as expressive of its various characters, and mode of origin. Thus, Pulpal Gangrene, Phagedænic Gangrene, Sloughing Phagedæna, Putrid Ulcer, Pourriture, Contagious Gangrene, and Hospital Sore, are severally synonymous.

*Signs, and Diagnostic Characters.*—Overlooking the many phases of this gangrene, and regarding only its more constant phenomena, its nature is perhaps best expressed by denominating it, *essentially*,—*gangrenous* inflammation; that is to say, inflammation certainly, but inflammation passing at *once* into gangrene, thereby appearing only a process of textural disintegration and disorganization. Sometimes the process of destruction resembles more that of phagedæna, alternating with rapid sloughing; so that the worm-eaten phagedænic surface suddenly becomes a large slough, and then again phagedænic. These different aspects of the disease are apt to mask its really gangrenous character. What, then, are the phenomena more constantly observed? Acute pain, sudden engorgement and bloated swelling, dusky-red discoloration around the doomed part, and conversion of its textures into a putrid glutinous or slimy slough, exhaling a peculiar fœtid odour. Rapidly extending, all the soft textures are soon melted down, leaving

only the bones staring, of an ebony black,—as if the rafters of a house where a fire has raged.

These *general* characters are clearly visible in the portraits of this disease, drawn by eye-witnesses; varied, however, by special circumstances; principally, by the previous kind of injury to the part affected, the textures engaged, and the constitution of the individual.

*Origin and Course.*—To identify this gangrene under the modifying circumstances referred to, it is necessary to trace its origin and progress—in a stump after recent amputation, as an incised wound, or granulating as an ulcer, a recent gunshot wound, a small puncture, an old sore, and lastly, a blistered surface.

For the particulars of these six aspects of Hospital Gangrene, I avail myself, chiefly, of Blackadder's original and valuable treatise.

(1) When a *stump* is affected, and the patient has a plethoric habit, or is accustomed to live freely, intense inflammatory action soon runs through its whole substance; swelling rapidly increases, so that in a few days the stump acquires more than twice its former size, and being much indurated, occasions the most excruciating pain. In this state the patient may become delirious, and die suddenly by effusion into some of the larger cavities. More frequently, however, gangrene seizes upon the integuments and cellular texture, large sloughs are thrown off, and some of the larger blood-vessels giving way, the patient sinks under the exhaustion of repeated hæmorrhage. For it is commonly found that the usual modes of stopping hæmorrhage from a stump are in such cases either inadmissible or totally inefficacious. Sometimes the progress of the disease in a stump is more *gradual*, yet ultimately nearly as fatal—*inflammation* is much less acute—there is comparatively little tumefaction, and the pain is far less severe; but the discharge is much more copious, and the cellular texture connecting the integuments and muscles is rapidly destroyed. Hæmorrhage generally supervenes later than in the preceding instance; it is, however, the most common cause of death. Sometimes, a stump, almost soundly *cicatrizied* to all appearance, will suddenly burst open and undergo gangrenous disintegration. Such cases are well described by John Bell.\* In one day he saw three stumps burst open, each of which had so nearly cicatrized, that you could have covered the small spot remaining unhealed with the tip of the little finger.

When this gangrene supervenes after any amputation, the case may be regarded as that of an *incised wound*, healing probably by adhesion, but suddenly diverted from primary union, and undergoing the aforesaid process of destruction.

(2) Observe the same gangrenous inflammation supervening on a healthy *granulating* wound, or ulcer.† The ulcer becomes painful and swollen, loses its healthy florid appearance, while the granulations, which were small and distinct, become flabby, and in some cases appear as if they were distended with air; in others, vesicles containing a watery fluid or bloody serum, have been observed, and the sensation in the sore has been described as resembling the stinging of a gnat. The secretion of pus is arrested, and the surface is covered with a tenacious viscid ash-coloured matter, which adheres firmly. After some time a discharge

\* Principles of Surgery, ed. Charles Bell, 1826, vol. i. p. 144.

† Observations on Hospital Gangrene, with reference chiefly to the Disease as it appeared in the British Army during the late War in the Peninsula. John Boggie, M.D., 1848, p. 42.

of thin ichorous matter ensues, a very peculiar cadaverous febrile smell, the pain increases, the edges of the sore are reverted, and generally assume a circular form; an erysipelatous redness encircles it, extending possibly to a great distance, even over a whole limb; the neighbouring glands, as those of the axilla or groin, swell, inflame, and perhaps suppurate. Omitting the constitutional symptoms thence arising, the local inflammation goes on apace, thin ichor continues to be discharged in great quantity, and a thick slough, apparently of coagulable lymph, like melted tallow, covers the whole surface of the sore, the fœtor is intolerable and the pain insupportable. At last an oozing hæmorrhage soaks the dressings, or a larger blood-vessel having sloughed, robs the patient of his last remaining source of strength, and the typhoid constitutional commotion soon terminates in death. Blackadder noticed that when the disease attacks a *large* recent wound, its whole surface may be affected at once; while in other cases, the gangrene commences on, or near, the lips of the sore.

(3) Passing from incised to *contused* wounds, "when," says this authority, "the disease attacks a *recent gun-shot wound*, the discharge, two or three days after contagion, is found to be lessened, and to have become more sanious than purulent. The sore has a certain dry and rigid appearance, its edges are more defined, somewhat elevated and sharpened, and the patient experiences in it a stinging sensation, as if occasioned by a gnat. Then, or a day or two later, the integuments at the edge of the sore become inflamed, and the surface of the sore itself assumes a livid or purple colour, and appears covered with a fine pellicle, such as forms on coagulating blood."

(4) "When," observes Blackadder, respecting hospital gangrene attacking a *puncture* or scratch, "the morbid matter is thus inserted, its first appearance resembles that of a part inoculated with *vaccine virus*." The primary inflammation begins at the end of the second, or early on the third day; it reaches its height about the sixth; but when the scab begins to form in one disease, *phagedænic* ulceration begins in the other, and if allowed to proceed soon affords sufficient proof of the non-identity of these diseases.

(5) Should the disease attack an *old sore*, where a considerable depth of new texture has been formed; a vesicle arises, filled with a livid or brownish-black fluid, which bursts and assumes the appearance of a small dark-coloured spot. Such vesicle, or spot, is usually situated at the edge of the sore. Phagedænic ulceration, spreading therefrom, makes comparatively very slow progress through the surface-bed of new texture, but having reached the subjacent natural texture, its progress is suddenly accelerated, acute inflammation supervenes, and a large slough forms.

(6) Lastly, when attacking the skin from which the *cuticle* has been removed, as by a blister, one or more small vesicles first appear, filled with a watery fluid, or bloody serum of a livid or reddish-brown colour. The situation of this vesicle also is generally at the edge of the sore. Its size is not unfrequently that of a split garden-pea, and is easily ruptured, the pellicle which covers it being very thin. If the vesicle contain a watery fluid, and has not been ruptured, its appearance resembles a greyish-white slough; if containing a dark-coloured fluid, or if ruptured, it appears a thin coagulum of blood, of a dirty brownish-black colour. During the formation of the vesicle a painful sensation in the sore is generally experienced, like that of a gnat stinging.

Thus the earliest and most elementary phase of Hospital Gangrene may be *vesicular*; just as gangrene generally begins, and senile gangrene in particular. The features peculiar to, and characteristic of, this so-called Hospital Gangrene, ensue *subsequently*—its slimy slough, its rapid progress, its appalling devastation. I shall presently have to notice one character which foretells all the rest, I mean *propagation by contagion*, and possibly by infection also, whereby the disease runs through a whole ward—a whole hospital if unchecked, passing from bed to bed with the rapid strides of death.

The *local results* to be anticipated are always sad, sometimes shocking. Among Blackadder's cases; in one, half of the cranium was denuded, the bones were black as charcoal, the integuments detached posteriorly to the second cervical vertebra; anteriorly, to the middle of the zygomatic process of the temporal bone; and this was originally only a superficial scalp wound. In another case, the integuments and cellular texture, on the anterior parts of the neck, were destroyed, and the trachea laid open, presenting a horrid spectacle. Among John Bell's cases, in one, the skin and muscles were carried away from the shoulder down to the bellies of the supinator muscles; and eventually, when the sloughing terminated, nothing seemed to be left of the arm except the bone, covered with a velvet-like surface of shining red flesh; and this was originally only a narrow splinter wound on the middle of the outer side of the arm. Continuing our course down the body; in one case, a very slight and superficial wound of the thigh grew into a sore, at first no bigger than the palm of one's hand; in two days as large as the crown of a hat; and in a week the whole skin of the thigh was destroyed, the muscles were stripped of skin and fascia from the hip to the knee, the trochanter was almost laid bare, the hamstring muscles were exposed to a considerable extent, and all the muscles of the thigh dissected in a manner which no drawing could express. With even these cases in view, imagination will scarcely realize the ravages of this gangrene. A tattered skeleton, still held together by ligaments? No; for the joints may be laid open extensively, and the knee, ankle, elbow, or wrist disarticulated.

*Constitutional Disorder.*—Long before any such irreparable injury has been inflicted, the constitutional powers take affront. The period, however, at which the constitution begins to exhibit symptoms of irritation is extremely irregular, sometimes as early as the *third* or *fourth* day, sometimes as late as the *twentieth*. The countenance assumes an anxious or feverish aspect; the appetite is impaired; thirst succeeds, and the tongue is covered with a white mucus. Some constipation at first, ends in diarrhœa. The pulse is rather irritated than accelerated. The general symptoms, however, have an inflammatory or typhoid character, according as the causes of either predominate. When an inflammatory diathesis prevails, the system becomes gradually more irritated, until acute inflammation attacks the sore, an event that frequently happens about the end of the second week. At this period the pulse is frequent and sharp, and not uncommonly the patient undergoes one or more shivering fits, succeeded by great increase of heat, seldom or never terminating in a profuse perspiration. The cold fit is sometimes followed by a bilious intestinal evacuation, with mitigation of the febrile disorder. If the local mischief be not arrested, weakness increases daily to exhaustion; the fever loses its inflammatory character, and unless the patient be cut off by hæmorrhage, he falls a victim to extreme debility. When the

disease has a typhoid character, the pulse is small and frequent, the appetite and strength gradually fail, not unfrequently diarrhoea supervenes, and the patient at length sinks, retaining his mental faculties to the last.

*Causative Relation of the Local and Constitutional Conditions.*—Whether does the constitutional disorder or the local disorganization precede? What is the order of succession; which is the cause; which the effect? Authorities are nearly equally divided on this question; but the weight of authority decidedly preponderates in favour of the local origin of hospital gangrene.

(1) *Local Origin.*—Blackadder affirms—"that in no single instance which I had an opportunity of observing, did the constitutional symptoms precede the local; unless the case be held an exception, where a stump became affected after amputation had been performed, on account of the *previous* effects of the disease.—That the morbid action could almost always be detected in the wound or sore previously to the occurrence of any constitutional affection.—That in several instances the constitution was not affected until some considerable time after the disease had manifested itself in the sore.—That when the disease was situated on the lower extremities, the lymphatic vessels and glands in the groin were observed to be in a state of irritation, giving pain on pressure, and were sometimes enlarged before the constitution showed evident marks of derangement.—That the constitutional affection, though sometimes irregular, was in many cases contemporary with the second, or inflammatory stage.—That when a patient had more than one wound or sore, it frequently happened that the disease was confined to one of the sores, while the other remained perfectly healthy, and this even when they were at no great distance from each other."

To these five arguments three more may be gathered from Welbank's well-known essay,\* forming so much additional support in favour of the local origin of this disease.—Thus the fact of its earlier stages being attended with little or no constitutional disturbance, was also noticed and urged by Welbank; and, "that when such disturbance does supervene, from the increased extent of the local malady, and unites in alliance doubly subversive of healthy processes of resistance, the latter stages of the disease are progressively accelerated.—That part of the diseased surface may clear off and granulate, while gangrenous disorganization continues progressive at the opposite edge.—That, however advanced the sore, it not unfrequently becomes healthy, and rapidly so, on the application of appropriate local measures;" and, "that the symptoms of general disturbance also which supervene are promptly relieved by measures that control the local condition."

Partly at variance with these facts and arguments, is the experience of Guthrie,† "That the febrile symptoms do seem to follow the appearance of the local alteration, is, in many cases, indisputable; that they precede or accompany the local symptoms in many other cases, is indisputable; and that the disease in a mild state, although capable of committing much mischief, is neither preceded nor followed by febrile or constitutional symptoms, cannot be doubted."

(2) *Constitutional Origin.*—On the other hand, there are, or have been those who affirm that the constitutional disorder generally, at least, *pre-*

\* Med.-Chir. Trans., vol. xi., 1820.

† Commentaries on the Surgery of the War in Portugal, &c., 1855, p. 165.

*cedes* the local disorganization. Thus, John Bell wrote :\*—The hospital sore is usually preceded by a degree of fever. Thomson—writing also from his own observations—states,† that these two classes of symptoms—the local and constitutional—are not invariable in the order of their appearance; for sometimes the one, and sometimes the other class, seems to occur first in the order of succession; but that the constitutional symptoms usually precede the local. Hennen also advocated this doctrine even more strenuously.

The question of local or constitutional origin may be further examined by reference to the known causes of hospital gangrene.

*External Causes.*—All observations respecting the etiology of this disease agree in certain particulars; that it is not developed epidemically, but rather as an *endemic*, springing up in some way among those who become affected. Thus, newly-built hospitals are free, so also are generally those built on high ground; while the disease arises in crowded and ill-ventilated hospitals.

*Infection.*—Thomson regards the disease as possibly infectious. "I have seen (says he) hospital gangrene introduced into an hospital by a single individual, and, when proper precautions were not taken, spread extensively among the other patients, but chiefly among those who lay nearest in the ward to the person originally affected or among those who had had most frequent intercourse with him. I have also known patients attacked in succession with hospital gangrene who had used the same bedding, or who, without using the same bedding, had occupied in quick succession the same small apartment." *Fomites*, therefore, can convey the infectious matter, and retain it some time. So highly infectious is this disease, according to Boyer's observation,‡ that it broke out in wounded patients, who, hoping to escape, had quitted the infected hospital, and retired to elevated situations where they breathed the most salubrious air.

The *infected distance*, or range of the contaminated air from the focus of infection, is unknown; but the disease certainly attacks patients at some distance apart (Thomson). Nor is the period of latency, after infection, more exactly determined. "I think (says this author), I have repeatedly seen the disease attack patients in less than three days after they had been exposed to its influence."

The production of hospital gangrene by infection seems to be disproved by Blackadder's observations, and chiefly by the result of the following experiment. He placed three patients with clean wounds alternately between three other patients severely affected. Their beds were on the floor, and not more than two feet distant from each other; but all direct intercourse was forbidden, and they were made fully aware of the consequences of inattention to their instructions. The result was, that not one of the clean wounds assumed the morbid action peculiar to the disease, nor was the curative process in any degree impeded.

*Contagion.*—This mode of communication can be traced as the *only* cause, in all cases since the days of La Motte, 1722, and Pouteau, in whose posthumous works, published 1783, hospital gangrene was first specially noticed. Pouteau observed that it may be communicated to the most healthy wound or ulcer in a person of the best constitution, and breathing the purest air, by merely placing in contact with any such

\* Principles of Surgery, ed. cit., vol. i. pp. 142, 147. † Inflammation, p. 458.

‡ Traité des Mal. Chir., tom. i. p. 322.

wound or ulcer, sponges, lint, &c., contaminated by contact with a sore undergoing the disease. Thomson concurs in the accuracy of this observation as well as advocating the infectious character of hospital gangrene. Delpech\* traced its propagation in almost every instance to the direct application of the morbid matter to the sores. Blackadder also recognised this mode of propagation in ninety-nine cases out of every hundred. Welbank arrived at a precisely similar conclusion. He speaks of the disease as being highly contagious by using the same sponges to different patients.† And Guthrie specifies this as one of the "conclusions"‡ of his observations during the Peninsular War. Nay more, that it is contagious through the medium of the atmosphere applied to the wound or ulcer.

Boggie's experiences§ during the same war compelled him to admit that hospital gangrene may be propagated by contagion, although he is disposed to attribute less importance thereto than to the continued operation of other local causes of an irritating character, in the shape of dirt, acrid applications, motion or mechanical irritation, attributing also considerable importance to other stimulating causes affecting the constitution; as hot weather, stimulating food, and the intemperate use of wine and spirituous liquors. In short, Boggie considers it inflammatory gangrene, and recommends antiphlogistic regimen.

While, however, admitting that all such causes may *predispose* to hospital gangrene, it does not arise in numberless instances where these and similar causes are conjoined in full operation. Their essential importance, therefore, cannot be allowed.

The etiology of hospital gangrene is so far obscure that its cause or causes, in the *first* instance of its occurrence, require further elucidation.

The general conclusion is this:—The disease may possibly arise from over-crowding in an ill-ventilated hospital or other institution; and is perhaps communicated by infection, from the sore itself emitting a poisonous exhalation; but it is assuredly also propagated by contagion.

*Treatment.*—Guided by the etiology of hospital gangrene, the nature of our *preventive* measures is at once suggested. When the *first* case appears in any hospital or other institution, our immediate object is to decompose the poisonous slough and discharge, and, moreover, arrest the progress of gangrene. Strong caustics such as will fulfil these intentions, should therefore be forthwith applied. Arsenic was originally recommended by Blackadder. The liquor arsenicalis, or diluted with an equal quantity of water, or with twice that quantity, was used, according to the emergency of the case. Strong nitric acid was first employed by Welbank. Either of these caustics, or even the actual cautery, should be applied until a new, hard, dry slough is formed, encrusting a clean and healthy surface. To prevent the *propagation* of this gangrene, punctilious cleanliness as regards the hands of the dresser, lint, water, and other appliances, should be daily observed in dressing all other wounds, even the most trivial and healthy. The bedding, also, should be changed, and clean linen furnished, as often as may be necessary to prevent their impregnation and the accumulation of fomites. Free ventilation and isolation of the patient will have similar preventive efficacy, and

\* Mém. sur la Complication des Plaies et des Ulcères comme sous le nom de Pourriture d'Hôpital, 1815.

† Op. cit.

‡ Commentaries on the Surgery of the War in Portugal, &c., 1855, p. 171. § Op. cit.

should not be neglected, although the disease may not be assuredly infectious.

*Constitutional* treatment must have reference to the combined state of irritation and debility; by the administration of opium, quinine, and stimulants.

The protective value of these measures has long since been fully established by their results. Thus, in military hospitals, the disease is apt to occur. Yet my own experience in respect of hospital gangrene, as it appeared during the late war, in the hospitals in the Crimea and at Scutari, does not approach what was formerly daily observed in *civil* hospitals. In the Hôtel Dieu, for example, it raged without intermission for two hundred years—so much so that “a young surgeon,” says an ancient French author, “who is bred in the Hôtel Dieu, may learn the various forms of incision, operations too, and the manner of dressing wounds; but the way of curing them he cannot learn. Every patient he takes in hand must die of gangrene.” Now-a-days, such scenes have passed away like a dream. This disease has not been witnessed for many years in the hospitals of this country, excepting on two occasions,—in the Middlesex Hospital, 1835,\* and in the University College Hospital, 1841.† With these exceptions, true hospital gangrene—contagious gangrene—has not reappeared; and many experienced surgeons of the present day have no practical knowledge of it whatever. The disappearance of a disease, once so frequent, once so formidable, can only be attributed to its causes having since subsided; and they are precisely the circumstances that have been specially obviated by the hygienic arrangements of the well-appointed and well-regulated hospitals of recent years; nevertheless, we are still bound to recognise hospital gangrene and to remember its etiology, as the best security for our continued observance of those protective measures which can alone prevent the recurrence of this disease in future.

## CHAPTER XI.

### POISONED WOUNDS.

#### HYDROPHOBIA.

HYDROPHOBIA is the constitutional disorder in the human species which arises from *contagion* with the saliva of a rabid animal.

Formerly, the reality of a *hydrophobic virus* was doubted, and even now-a-days the importance of a well-grounded belief on this starting-point must be obvious in relation to the appropriate means for preventing the consequences of the bite of a rabid animal. The dog and cat, and other animals of the canine and feline species, are peculiarly prone to hydrophobia; and there is abundant evidence to show that the bite of a “mad dog, cat, wolf,” &c., induces this disease by virtue of the *saliva* thus introduced.

The *wound* itself is often trivial—a mere scratch or graze from a tooth of the animal in the act of snapping; yet a very large proportion of

\* System of Surgery, Chelius, trans. by South.

† Lancet, 1845, vol. i., Lectures, Liston.

persons bitten by a rabid animal undergo hydrophobia, sooner or later, and die; and it is incredible to imagine that so many individuals, differing in their constitutional idiosyncrasies, should alike experience the same constitutional disorder, and that a fatal one, from a wound scarcely worthy of the name. The (morbid) saliva introduced by a scratch, itself trivial, is the only *peculiarity* of such lesion, and a very significant one. Many recorded facts, read in this light, become intelligible. Of fifteen individuals bitten by a mad dog, and attended at Senlis, by the Commissioners of the French Royal Society of Physic, ten were bitten on the naked flesh, and five through their clothes. Of the former, five proved fatal. Near Rochelle, twenty-four persons were bitten by a rabid wolf, and eighteen of them perished.\*

The existence of a hydrophobic virus, in the shape of a peculiar morbid saliva, has been also demonstrated *experimentally*. Several animals were inoculated with the saliva of a rabid dog, recently dead; a dog, a cat, a horse, and a cock were thus infected by Dr. Zine. Dupuy, in like manner, induced the disease by taking a sponge, which had been bitten by a mad dog, and rubbing it on the open sore of a sheep. Youatt drew a silk thread backwards and forwards through the mouth of a rabid animal, and having inserted it as a seton in the neck of a sound dog, this animal subsequently died of hydrophobia.

If, then, the inoculation of a peculiar virus be indisputably the cause of hydrophobia, is this disease capable of being conveyed by clothes impregnated therewith? Can it be communicated by *fomites*? Clearly so; for a dog's tooth is itself a fomes. To this effect, also, Mr. Trevelyan, writing to Dr. Bardsley, states that, after losing one pack of hounds by rabies, he not only removed the straw, but had the benches of the kennel scalded with boiling water, and afterwards all the joints painted and filled up with hot tar; the walls were then whitewashed, and the pavement cleaned with hot water. Thus secure as he imagined, he collected another pack; yet rabies again broke out and recurred year after year. In consequence of these continual attacks, he removed the pavement, threw the earth beneath into the river, refitted, new painted, and whitewashed the kennels; ever after which the pack continued perfectly healthy.

The *saliva* of a rabid animal being the source of hydrophobia by contagion, explains many things otherwise anomalous. This virus is usually introduced through a bite of the animal diseased, but the mere application thereof to ever so slight a wound, scratch, or other solution of continuity, in an *absorbing* surface, is sufficient. In such case, the lick of a rabid dog generally induces hydrophobia. The surety of inoculation will obviously be affected—by the number of wounds inflicted, by lodgement of the virus or its escape by hæmorrhage; and above all, by unobstructed inoculation through the naked flesh as compared with the protection offered by clothes. Apart from these modifying circumstances, in some cases no evil consequences ensue from the bite of a rabid animal, and the immunity enjoyed must be ascribed to some unknown peculiarity of constitution.

*Local Condition.*—Overlooking exceptional cases, hydrophobia ensues in a variable period from the date of the reception of the virus. The wound has generally healed, or it may not have healed quite soundly.

\* *Recherches sur la Rage*, Audry, ed. 3, p. 196.

In either case, slight pain of a rheumatic character shoots from the site of the bitten part to some distance; so that if the hand be the part first affected, the pain extends up the arm and shoulder, fixing itself in the trapezius muscle probably, or the proximate side of the neck. Sometimes a tingling heat, or even a sensation of cold, is experienced, rather than pain; but either sensation equally *extends*,—say, up the arm and shoulder. Generally, actual pain is felt, and eventually shooting towards the heart. Meanwhile the cicatrix swells, reopens, and discharges an ichorous matter. Occasionally no local symptoms occur; neither the customary radiating pain, nor any inflammatory condition of the cicatrix.

*Constitutional Disorder.*—After the lapse of some days perhaps, other and more formidable, because constitutional, disorder begins. The nervous system, together with its ally, the muscular, are the subject of all those phenomena which characterize this affection. The cerebro-spinal axis acquires undue susceptibility. Rapid-flowing thoughts, reviving memory, and fertile imagination, are expressed by a more animated manner and conversation; although, in some cases, a downcast pensive mien, yet withal irritable and peevish manner, prevails. Far more frequently, however, thoughts and fancies whirl through the brain tumultuously. A dull heavy pain caps the head and oppresses the temples, light is intolerable, and the slightest noise jars the whole frame; while sleepless nights or starting dreams, an overwhelming dread, muscular twitches, and pains in the neck, back, and limbs, complete the picture of morbid excitement—bordering on delirium. This state of comparative ease lasts only four or six days, possibly only a day or two; when the most remarkable symptom of true hydrophobia supervenes,—an *indescribable dread of fluids*; any attempt to drink—even the sight or sound of water, the thought of it, or anything associated therewith, as the noise of tea-cups, or of a pump—immediately excites a convulsive paroxysm, threatening suffocation. In some cases the slightest breath of air, a fly settling on the face, or a bright light, has the same effect.

These convulsive attacks are *paroxysmal* with *complete* intermissions. A viscid mucus accumulating in the mouth occasions an *incessant action of the lower jaw* to extricate it. The pains now piercing the epigastric and præcordial regions, more particularly, the general sensibility, becoming more and more acute, and the convulsive paroxysms more frequent, desperate and protracted, soon exhaust the patient's bodily power, while his mind is hurried on to *furious mania*; and thus, when fighting for breath, or utterly worn out, the poor sufferer expires. The second or third day usually brings this happy release. It may be postponed to the fifth or sixth day. Age makes some difference, for children endure not longer than twenty-four hours generally.

*Diagnosis.*—I have italicised those symptoms which, contrasting with the phenomena of tetanus, serve to distinguish hydrophobia. To these characteristics may be added two more;—the *early* period of *death* from rabies as compared with tetanus, and its *longer* period of *latency*. On this point, however, considerable extremes are recorded.

*Period of Latency.*—In one hundred and thirty-one cases, none of the patients became ill before the eleventh day after the bite, and only three before the eighteenth day. In two hundred and twenty-two cases, the disease showed itself eleven times before the tenth day; twenty-one, between the tenth and twentieth day; twenty, from three to six weeks; eighty-nine, from seven weeks to seven months; eighty-nine, from seven

months to twenty-seven months; one, after four years; one, after five and a half years. In Hamilton's table, it occurred in seventeen cases, between eighteen and thirty days; in sixty-three, between thirty and sixty days; in thirteen, between three and six months; in seventeen, between six and twelve months; in four, from ten to twenty months.

In both these series the period of incubation extended to between the third and eighth week. The extreme periods, as determined by Dr. J. Hunter, were thirty-one days and eighteen months. The most extensive and authentic observations accord about *forty days* as the *mean* period of latency in the human subject. Here, then, is a season during which *preventive* measures can be employed with the prospect of success.

*Treatment.*—Prompt removal of the hydrophobic virus by the cupping-glass, and free excision of the bitten part, constitute the most effectual preventative. In a part so situated that excision is impracticable, free cauterization may be resorted to, with strong nitric acid, potassa fusa, or nitrate of silver. It is impossible to say how late, in the period of incubation, these means would prove successful; for, if not employed in any given instance, some constitutional peculiarity might itself avert the super-vention of hydrophobia. There is just this poor chance of safety. But, considering the very large proportion of cases in which the disease does inevitably arise, no time should be lost. Excision, therefore, should be practised at the *earliest* opportunity, and not postponed, however long it may have been neglected; provided, of course, that in either case there be sufficient reason for believing or suspecting that the bite was inflicted by a rabid animal.

Before, then, resorting to a measure which entails permanent mutilation, more or less; the state of the *animal's* health in question should at once, if possible, be inquired into. The dog and cat chiefly concern us in this country. Rarely is the rabid state any approach to the popular notion of a "mad" dog. No wild excitement appears, no savage tendency to bite, and certainly no dread of water, so remarkable in the human subject. Rather will suspicion be aroused on ascertaining that the animal evinces only some strange departure from its usual habits and manner. In very many instances this peculiarity is a disposition to pick up straw, bits of paper, rag, thread, or any small object in the way. The animal laps water greedily. A disposition to lick is noticed in some cases, and particularly to lick anything cold—cold stones, or the cold nose of another dog; great aversion, however, to strange dogs and cats, especially to the latter, is very commonly observed at an early period. Some such *unusual* propensity is soon followed by an *irritable*, peevish manner. The animal snaps those about it, and resolutely fights if the least provoked, soon becoming furious. When thus obviously dangerous, it is forthwith secured. Yet a dog dangerously rabid may be perfectly quiet and natural, save in respect of some unsuspicious, because unobtrusive, symptom. Allowed to run about, patted and played with as usual, it bites in an unguarded moment. In *this* state, therefore, as well as when obviously rabid, the animal should be at once chained up. Instead of being killed, it can then be watched, to ascertain the real nature of its indisposition; thereby determining the necessity for excision in the case of any person who has been bitten. If the animal be affected with rabies, it will probably die in a few days; and this operation is imperatively demanded, as the only means of preventing hydrophobia in any of the human species who, having been bitten, would otherwise perish eventually. The safe

custody of the rabid animal will also effectually prevent further mischief being done during his short period of probation.

Supposing an animal, not itself rabid, or bordering on that condition, to have been bitten—a healthy dog, bitten by another dog, decidedly rabid. The latter will, of course, be killed; but when may the former apparently healthy dog be allowed to go free? This question, bearing directly on the spread of rabies among animals, bears equally on the prevention of hydrophobia in the human species, by eradicating the source of this disease.

The question turns on the period of latency among *animals*. In the dog it is considered to terminate about the end of the sixth week. At the Veterinary School, Alfort, when a dog is bitten, it is chained up for fifty days, and, if healthy at the end of that period, is restored to its master. Mr. Samuel Cooper used to mention in his lectures, at University College, an instance of a more extended period than that which regulates the preventive measure adopted at Alfort. A large Newfoundland dog, having been bitten by another dog, did not become rabid until seventy days had elapsed; information the more valuable, since Mr. Cooper himself watched the case from beginning to end. In Lord Fitzwilliam's pack the disease appeared at various intervals, from six weeks to six months.\* We may therefore conclude, that an animal bitten by another in a rabid state should be chained up for a longer period than the experience at Alfort would suggest as an adequate preventive injunction—imprisonment for six weeks.

Preliminary to this question is another—the *communicability* of hydrophobia or rabies among animals and man,—a consideration essentially relating both to its propagation and prevention. Many facts tend to show that the communicability of this disease depends on the inherent capability of the animal affected to *engender* it spontaneously; failing which, he may bite in vain. The dog can generate rabies, and therefore can communicate it to another animal, or to man, in the shape of hydrophobia. Sheep, horses—the herbivora—and man cannot generate the disease, and therefore cannot communicate it. Thus, rabies in a flock of sheep, consequent on the bite of a rabid dog, is not communicated from one sheep to another, although the sound are often bitten by the diseased, and in parts stripped of wool (Dupuy). At the Alfort Veterinary School three sound sheep, two dogs, and a horse were inoculated with the saliva of a rabid horse; not one of them became affected. In keeping with this view, man cannot communicate hydrophobia. By the experiments of Vaughan and Babington, animals were inoculated with the saliva of hydrophobic patients, but without any effect. In an exceptional experiment by Magendie and Breschet, one dog of two thus inoculated became affected; but this animal might have been previously diseased, especially as rabies was rife at the time. Paroisse inoculated three dogs with the saliva of a man in hydrophobia; the animals were kept and watched for nearly four months afterwards, during all which time they remained quite unaffected. Similar experiments were conducted by Gauthier, Giraud, Girard, and Bezard, with the same negative results. Lastly, there is no instance of one human being acquiring hydrophobia from another labouring under this disease, although in many instances attendants have been bitten by such persons.

\* Morbid Poisons, R. Williams, M.D.

In conclusion, the general inference to be drawn from these facts is this—that in estimating the danger to human life incurred by the liberty of rabid animals, those only which can generate rabies—*e.g.*, the dog—are dangerous. The human species affected with hydrophobia is harmless, should there be any tendency to bite.

Such considerations, coupled with a due knowledge of the duration of latency in different animals, particularly the dog, suggest adequate precautionary restraint; while, in the event of hydrophobic virus having been communicated to man through the bite of a rabid animal, the prevention of the disease then impending is fulfilled by free excision of the part bitten, as soon as possible, aided, if necessary, by cupping.

*Curative* treatment will be utterly useless, although it may be possible to palliate symptoms and prolong life. This may perhaps be effected by the plan of treatment recommended by Marshall Hall and Todd. It consists in removing all causes of irritation, bodily and mental, as by placing the patient in a darkened room, excluding any draught of cold air, all noise and conversation. The application of an ice-bag along the whole length of the spine seems to have some influence in allaying the excitability of the cord; while stimulants and nourishment support the patient in the exhaustion consequent on the convulsive paroxysms.

**SNAKE-BITES.**—Of Poisoned Wounds, in the ordinary sense, the bites of venomous snakes, happily of rare occurrence in this country, possess much surgical interest; chiefly with the view of preventing their constitutional effects, rather than the more hopeless intention of curing them. The local effect of a poisoned wound is essentially *cellulitis*; inflammation of the subcutaneous cellular texture, announced by acute burning pain, accompanied with some, and perhaps, subsequently, enormous diffused swelling, not at first involving the skin. In severe cases the swelling spreads rapidly, and to an almost unlimited extent, so widely may it range.

The bites of the rattlesnake and of the cobra di capello answer to this general description.

*Local condition.*—A piercing pain is immediately felt, rapidly shooting through the limb; swelling quickly succeeds, and a mottled livid redness, indicating that the skin is now involved. The cellular texture of the whole limb, and perhaps down the proximate side of the trunk, becomes gorged with a bloody sanious fluid; and, as if to relieve this tense yet diffused swelling, phlyctenæ arise here and there. Very shortly the pain abates, the tension is exchanged for a flaccid softness, the limb is cold and benumbed; while patches of gangrenous skin announce that the work of destruction has commenced, not however disclosing the ravages already wrought beneath the skin in the subcellular texture, and still less the extent to which it may eventually be sacrificed.

*Constitutional Disorder.*—Rapidly as all this mischief is accomplished, the constitutional disturbance begins almost concurrently with the first introduction of the poison. Soon after the poisonous bite has been inflicted, symptoms of muddling intoxication ensue. The victim mumbles incoherently, and staggering, as if dead-drunk, is overcome with helpless prostration and oppressed breathing. Other and even peculiar symptoms are witnessed. Profuse cold sweating, bilious vomiting, and perhaps evacuations of bile; while a yellow hue overcasts the skin. Excruciating pain about the navel is sometimes experienced. The pulse quivers irregularly, the nervous system succumbs to the potent poison, and the sufferer expires.

Now, in order to prevent this fatal issue, and, moreover, the formidable antecedent symptoms, remember the poison begins to operate almost immediately, varying in this respect, however, with the dose. Still its period of latency is short.

*Period of Latency.*—In one case—carefully recorded by Sir E. Home\*—a man was bitten by a rattlesnake at half-past two P.M., and brought to St. George's Hospital, by three o'clock; during this brief period of only half an hour the constitutional disturbance had become overwhelming; and in the interval, when the man went of his own accord to a chemist's shop for relief, he was observed to stagger, and appeared drunk. Death ensued. In another instance,† the bite of a rattlesnake began to manifest its effects within the first half hour.

*Treatment.*—If we assume the period of latency to be *under half an hour*, preventive measures should be very promptly employed. The poison may be removed from the bitten part, or arrested before entering the general circulation or neutralized. The application of a cupping-glass, or excision, are calculated to withdraw the poison; a ligature above the part affected, fulfils the second purpose; caustics, the actual cautery included, the third purpose. Of these appliances, that of cupping is most efficacious and practicable, if not the only one of value.‡ Diffuse inflammation consequent on the introduction of the poison, must be treated by free incisions and fomentations. Curative treatment has very little effect in overcoming the constitutional condition of utter prostration. Stimulants, such as brandy, wine, or ammonia must be freely administered. Arsenic, in large doses, has been recommended as a specific. Such is the "Tanjore pill," a famous Indian remedy. But its efficacy is doubtful and even perilous.

MALIGNANT PUSTULE OR CHARBON, is also communicated by *contagion*, the poisonous matter being caught directly from beasts, or their remains; for the disease is not propagated apparently by the human species, from one individual to another.

*Local condition.*—Soon after any accidental inoculation with the morbid matter, a stinging sensation is felt, and a red point appears, hardly elevated above the skin. Then, at this point, the cuticle rises into a blackish vesicle, which speedily runs into a slough, surrounded by an œdematous swelling, having a violet tinge, and spreading rapidly in all directions. Occasionally, neither vesicle nor pustule arises, only swelling. Such was the character of the disease in three cases observed by Lawrence.§ With obvious swelling, however, a sensation of tension, rather than pain, is experienced. Should several pustules arise, the disease is proportionately more perilous, and especially if situated on the neck or face; for then the swelling may be so considerable as to threaten suffocation or congestion of the brain. Indeed, malignant pustule is not unlike carbuncle in appearance, but differs from it in being always the result of contagion. And this etiological consideration will always determine the diagnosis.

*Constitutional Disorder.*—A variable period having elapsed, the constitutional symptoms supervene. Fever, attended with pain over the stomach and vomiting, is soon succeeded by delirium and prostration.

‡ Experimental Researches on the Influence of Atmosp. Pressure on the Blood in the Veins, and on the Prevention and Cure of the Symptoms caused by the Bites of Rabid or Venomous Animals. D. Barry, 1826.

§ Lancet, 1825-6, p. 127.

The causative relation between the local lesion and this constitutional disorder is shown by their invariable sequence. The latter always follows the former; and, moreover, it is very doubtful whether the constitutional disorder can be induced by contact with the same morbid matter, unless succeeded by the formation of malignant pustule. This local lesion, therefore, would appear to be the *only* cause—the only mode of origin, of the constitutional morbid condition.

The nature of the morbid matter itself is unknown, but it is developed in beasts affected with “contagious carbuncle.” The poison may be imparted by any accidental inoculation, in handling the animal when alive, or during the manufacture of hides, wool, &c. Malignant pustule is consequently most rife among butchers, tanners, shepherds, and wool-beaters. It may also be produced by eating the flesh of animals thus diseased. Instances in proof of this mode of production are cited by Wagner and Turchetti. Temperature and moisture have apparently some influence, for the disease is most prevalent in damp localities, and in wet autumnal weather. The morbid matter—whatever it be—retains its poisonous power for a long time; but the disease is probably not propagated by the human species, from one individual to another.

*Treatment.*—Preventive measures are obviously suggested in accordance with the known etiology of this disease; although in the pursuit of certain avocations it may be difficult so to protect the hands and exposed parts of the body so as to escape contagion. Even then, however, this preventive opportunity remains; the progress of malignant pustule can generally be arrested at its commencement by excision or cauterization.

GLANDERS is another disease derived by contagion from certain *animals*—the horse, ass, or mule—similarly affected.

Inoculation of the human species is apt to occur by handling either animal when glandered; and the constitutional disorder thence arising may be briefly described as fever, resulting in the production of many inflammatory tumours in different parts of the body, which have a great tendency to suppurate and fall into gangrene. Towards the close of glanders, in 11 of 15 cases (Rayer), puriform mucus, mixed with blood, oozed from the nostrils; in 10 of these cases, the discharge came from one nostril only; and in all cases the quantity was inconsiderable, sometimes scarcely appreciable. The eyelids, also, are tumified, and secrete a thick viscid mucus. This disease runs its course in a period varying from a few days to many months.

Its *period of latency* in man varies from two to eight days.

*Treatment.*—I am not aware of any means whereby the progress of glanders can be arrested when once inoculation has taken place, however early our intended preventive measures may be applied. If in this respect unlike the bite of a rabid animal, a snake-bite, or malignant pustule, glanders has at least one advantage—the disease can always be *avoided*.

As bearing on the question of prevention, the early and exact diagnosis of glanders in *animals* is important. It is communicated to man by an animal in a state of disease so obviously characteristic that the danger cannot be overlooked.

Two varieties of this disease, in the horse, ass, or mule, are recognised by R. Williams. In *gangrenous* glanders, the animal immediately loses its spirits, and staggers; the nasal and conjunctival mucous membranes are beset with a number of red points, which at the end of twenty-four to

forty-eight hours, become livid; the nostrils now discharging a yellow matter, streaked with blood. This condition lasts two or three days; then the nasal membrane falls into gangrene, and large ulcers form where portions have sloughed. The discharge increases and exhales a fœtid gangrenous odour; œdema of the nostrils, scrotum, and legs soon supervenes: at length, the nostrils being glued together, respiration fails, and the animal dies. In *pustular* glanders, the same general debility and fever are observable as in gangrenous glanders. The specific inflammation of the nasal membrane is an eruption of pustules, said to resemble confluent small-pox, followed by a copious yellow viscid discharge from one or both nostrils. After two or three days, these pustules ulcerate, sometimes internally, so as to destroy the bones and cartilages of the nose. By absorption of the nasal morbid secretion, the sub-maxillary glands become swollen and tender, but only on the inflamed side of the head. Such enlargement is called the "kernels." Œdema of the nostrils, the sheath, and hind limbs succeeds, as in the gangrenous variety; and respiration failing, death ensues on the eighth or tenth day, at latest.

Glanders is often accompanied with "farcy," and farcy often ends in glanders.

*Button farcy* is characterized by inflammation of the cellular texture, forming tumours in different parts of the body; the head, neck, and extremities, particularly the hind legs. In four or five days they soften and ulcerate. It is an inflammation of the lymphatic glands and vessels, usually beginning in the hind extremities, attended with lameness, and forming an irregular swelling of the limb, which at length ulcerates and discharges a sanious fluid.

The *period of latency* in glanders affecting *animals* is generally short. Two asses—one about a year old, the other about a year and a half old,—were inoculated by Turner. In the former the maxillary glands became tender on the second day, and the discharge from the nostrils was established on the following day. In the latter the maxillary glands enlarged on the third day, but the nasal discharge did not appear until the sixth day. In a horse inoculated with farcy matter, the disease did not appear until the end of three months, and then precisely at the points of puncture. Gerard states that he introduced the matter of the discharge every day, at different times, into the nostrils of certain horses by means of a brush, and that the disease appeared on the seventh day, but in two others not until the thirty-second day.

Fortunately, however, glanders is not an eminently *contagious* disease, either from one animal to another, or from this source to the human species; and its *communicability* from one human being to another is very doubtful. A case once apparently occurred in St. Bartholomew's Hospital:—a healthy nurse contracted disease from a glandered patient, and she died after a short illness, having every symptom of glanders.

Assuming that glanders can be readily detected and distinguished from all other diseases, the prevention of its *first* propagation will consist in forthwith destroying the diseased animal from which, as the centre of contagion, it might spread. This preventive precaution is not alone sufficient protection to man or beast. The disease is communicable by *fomites*, as well as by direct inoculation from one animal to another. In this way, some of the discharge from the nose of a glandered horse having remained about the manger, rack, or partition of a stable, may be thawed by the breath of a new horse, or introduced into the system in the act of

nibbling or licking, whereby sound horses have speedily become glandered when put into a stable whence a glandered one had been taken weeks or months previously—thus reviving the disease, and with imminent peril to grooms and others in attendance. “Let, then,” says Youatt, “the halters, head-gear, and bridles be burned; the clothes washed and baked; the pails newly painted; the racks and ranges thoroughly scraped, then washed well with soap and water, and afterwards with chloride of lime and water, in the proportion of a pint of the strong solution to a pail of water; let the walls be well scraped and washed with the chloride of lime and water, then well lime-washed; the floor be first thoroughly scoured, then sluiced with the chloride: and, with all these precautionary measures, every possibility of danger will be removed.”

## DISEASES OF THE NERVOUS SYSTEM.

### CHAPTER XII.

#### SHOCK OF INJURY.—COLLAPSE.

**SHOCK.**—*Symptoms, and Diagnosis.*—Failure of the heart's action, or cardiac syncope, is the immediate effect of any sudden and violent impression on the nervous system. This failure of function is denoted by a thready, feeble, yet frequent and perhaps irregular, pulse; which is accompanied with pallidity, a cold clammy skin, haggard look, and lacklustre eye, great muscular prostration, soft sighing respiration, and, perhaps, some cerebral disturbance; symptoms which constitute the state known as Shock, or Collapse as arising from Injury. Other symptoms are exceptional and occasional only. Hiccup, vomiting, relaxation of the sphincters, attended with involuntary micturition and defæcation; suppression of urine, convulsions, and stupor.

It thus appears that in this state of functional suspension, both the nervous and blood-vascular systems are overwhelmed, involving possibly, all other functions; but, as the shock of Injury, the nervous system is primarily affected, and *thence* the vascular system; thus differing from cardiac syncope consequent on hæmorrhage. A great physiological relationship underlies the pathology of Shock;—namely, that while the action of the heart is independent of the nervous system, it is much influenced and even arrested by any impression through that system. Not unfrequently, however, with Injury, *both* modes of origin,—nervous suppression and loss of blood, co-operate.

*Causes—Injuries* of all kinds—*e.g.*, incised and lacerated Wounds, Burns, Fractures, and Dislocations—are attended with Shock; and according to their *extent* as involving the nervous system, and their *persistence* as causes in operation. A burn, superficial in itself, but extensively involving a considerable cutaneous expansion of the nervous system, will cause more extreme shock than a far deeper burn of limited nervous consequence. Unreduced Fractures and Dislocations continue to operate, by laceration and pressure, on the nervous system. But injuries of organs, abundantly supplied with nerves, or in intimate relation with the

nervous system, are equally influential. Thus, crushing of the testicle, or lesion of an internal organ, may prove fatal.

Simple shock, without any apparent structural damage, may be equally deadly. A blow, for example, over the epigastrium; or pain, intense and prolonged; a stroke of lightning or exposure to cold. Certain poisons, probably, have an action resembling Shock; such are powerful sedatives, as tobacco, and powerful purgatives.

Mental emotion may operate in like manner. Fear, or bad news, will cause the heart to sink in a moment, accompanied with the pallor of collapse; while, a depressing passion, such as grief, weighs it down more permanently.

*Predisposing* conditions are, perhaps, very influential. Impressibility to the causes of Shock is, however, not an indication of its continuance; but generally inversely proportionate. Thus, shock may be easily occasioned, yet soon pass off, as in *youth*; or not so readily occasioned, and yet persistent, as in *old age*. *Premature age*, by intemperance or sexual excess, is peculiarly unfavourable. *Constitutional susceptibility* is well marked, in the shock of some individuals; but it requires all the experience and judgment which the Surgeon can bring to his aid, to foresee this peculiarity. I remember removing a great toe-nail, under the local-anæsthetic influence of ice and salt; the patient being a robust, ruddy-complexioned young woman. She sat up during the operation looking at her foot, and experienced no pain then, nor much afterwards. Yet no sooner had the circulation in the toe returned, than she became blanched and cold, and subsequently fainted—alarmingly several times.

*Terminations.*—(1) A *fatal* termination may ensue almost immediately, and unexpectedly. I have seen a patient with severe compound fracture just removed to bed, restlessly attempt to raise himself once or twice, and then drop dead on the pillow. The heart's action is paralysed through the impression on the nervous system.

After death, the heart is found engorged with blood; all its cavities being distended, especially the right auricle and ventricle. The venous system, generally, is similarly distended. Coagulation has taken place to some extent, but imperfectly; a considerable portion of the blood remaining fluid, while the clots are loose and dark. Sometimes the blood is altogether fluid. Rigor mortis commonly occurs, and sometimes very strongly. A significant fact is the accumulation in the stomach, of any food which may have been taken, and that it has undergone little or no change; thus indicating the suspension of digestion, in common with other functions which can be observed during life. I have also frequently found the intestines comparatively empty, and singularly enlarged, owing apparently to atony of their muscular coats. Beyond these appearances there is a remarkable absence of any discoverable lesion apart from the injury itself, which has occasioned the shock. Considering the known dependence of all function on structure, it is highly probable that some molecular disintegration of nerve-tissue has occurred, which has hitherto eluded observation. This would not be inconsistent with the speedy recovery in many cases, by any such structural disorganization having returned to a healthy state.

(2) *Reaction.*—A natural restorative effort commonly ensues, in a period varying from a few minutes to thirty-six or forty-eight hours, or more. This reaction, as it is termed, of course implies the revival of those functions which have been temporarily suspended. The balance

of the circulation is regained, the pulse acquiring force and fulness, and losing its frequency and irregularity. With it warmth returns, and the colour of the living body reappears. Respiration becomes more perceptible, prostration is less marked, the individual evincing some inclination to turn from the supine posture, and the cerebral obscurity clears off. Ordinarily, I think, reaction is not a continuous restorative effort; but slight retrogressions towards collapse occur, followed by reactions progressively more and more complete; and it is by this series of ebbings and flowings, that the balance of the circulation and other functions is at length regained.

If revival be incomplete, a mixed state of exhaustion, with reaction, prevails.

*Prostration with excitement*—as this state was first named by Mr. Travers—is distinguished by a rapid bounding pulse, but weak and liquid. The skin is hot and the face flushed, but there is still a haggard expression. The breathing is hurried, and irregular, there is much restless tossing about, and perhaps spasmodic action of the muscles, with great debility, and the mind becomes excited and bewildered. The patient now dozes off, then flickers up, as it were, suddenly, with an agitated and tremulous manner, only again to wander, and again arouse. At length frenzy, possibly, subsiding in coma and re-exhaustion, with a cold clammy sweat, ends in death; or ultimately, reaction prevailing, the pulse regains its force, loses its frequency, and the healthy status is slowly re-established.

*Remote* constitutional consequences are said to occur after the shock of injury; resulting perhaps in sudden death, some weeks or months after apparent recovery. Hodgkin and James have directed attention to these consequences; but it is very difficult to connect them as such with the original shock.

The *prognosis* of shock is always precarious and uncertain. It will depend very much on the causes, immediate and predisposing, already mentioned. And here individual predisposition is a highly important criterion; and especially the natural calmness and hopefulness, or the irritability and despondency, of a patient. Watchful nurses recognise these distinctions in *their* prognosis, as well as surgeons. The explanation is obvious, that mental dispositions are not only predisposing, but also *persistent* and therefore maintaining causes of shock. Persistent conditions of bodily injury are likewise unfavourable. *Extent* of injury indicates rather the immediate intensity of shock, than the probability of its continuance.

*Treatment*.—This also should have reference to the cause or causes of shock. Some are slight and transient, and thence reaction soon follows. Others again are more severe and perchance persistent; whereby the shock being proportionately more intense and lasting, reaction is delayed, and imperfect. The removal of any cause still in operation is, therefore, obviously of primary, and in a measure, of preventive consequence. Hence, the reduction of fracture or dislocation, of strangulated hernia, and even the amputation of a severely injured limb, are of vital importance, in the treatment of shock.

Remedial measures take effect in proportion to the natural tendency to reaction, and this—apart from the continued operation of causes—is not immediate. The patient should be placed in the recumbent position, and stimulants administered to further aid the returning circulation.

Warm tea for children, brandy or ammonia and water for adults, may be given, provided the patient can swallow; otherwise, with insensibility, the fluid may pass into the larynx and cause suffocation. Watching the effect on the pulse, stimulants must be repeated from time to time as occasion requires. Volatile ammonia held to the nostrils is temporarily restorative, but it may be thus administered when fluids cannot be swallowed. Then also, a stimulating enema, of turpentine for example, will be an advantageous mode of stimulation. In all cases, warm blankets, hot bottles to the feet and epigastrium, and perhaps galvanism, are available and effectual. The possibility of over-stimulation, by any of the means employed, must not be overlooked; remembering that sensation, for a time, is in abeyance, we should, as Professor Miller expressed it, "feel for the patient." In apparently *hopeless* cases, artificial respiration, patiently continued, may be resorted to with success. Opening the external jugular vein, is recommended by Mr. Savory, in consideration of the engorgement of the right side of the heart and venous system. Collapse from the loss of blood by hæmorrhage from any cause, suggests the employment of "transfusion," as the special means of meeting this emergency. Nourishment also, to supply the loss of blood, is a more immediately urgent requirement than in ordinary nervous shock.

*Excessive* reaction must be met by opiates rather than blood-letting; the fever being nervous more than inflammatory. The substitution of light nourishing food for mere stimulants, will be found advantageous; for there is still a strange mixture of exhaustion with *such* reaction.

*Prostration with excitement*,—or the more pronounced phase of this condition, requires similar treatment. The quantity of opium borne with impunity, and eventually proving remedial, is often surprising. Grain doses of solid opium or equivalent doses of the tincture, may be administered repeatedly, at intervals, according to the symptoms; and with stimulants, in kind and quantities, also according to the symptoms, and the previous habits of the individual. Nourishing food should, as soon as possible, aid or supersede these more immediate resources. Not unfrequently, however, any food is almost rejected by a sort of hiccupy vomiting, a symptom which is in itself distressing to the patient. Small pieces of ice swallowed occasionally may afford some relief; and hydrocyanic acid, or creosote, are sometimes more useful.

The question as to the performance of a *Surgical operation during Shock*, is determined by two considerations;—the persistence, or not, of any cause in operation, as, for example, a bad compound fracture; and, secondly, the pathological fact, that the nervous system and circulation *already* in the state of Shock, is less susceptible of further shock than after reaction. An almost *immediate* surgical operation thus forms part of, and joins issue with the injury, for which it is performed. *After* that period of juncture, it is better to make a compromise with the vital powers, by waiting for *incomplete* reaction.

*Chloroform*, is detrimental, in proportion as Shock prevails, and equally useless, owing to the comparative insensibility of the patient.

## CHAPTER XIII.

## TETANUS.

TETANUS (*τείνω*, to stretch) signifies a violent and involuntary contraction of the voluntary muscles, attended with severe pain and rigidity.

*Symptoms, and Diagnosis.*—The spasmodic contractions having commenced, never entirely relax throughout the course of the disease; they are *tonic*, thus distinguishing them from intermittent or *clonic* spasms in ordinary convulsions, as in hysteria or apoplexy; and complete consciousness is retained to the last, this additional characteristic distinguishing the tetanic from clonic spasms in epileptic convulsions, and from those of hydrophobia.

Tetanus approaches and proceeds by the following series of spasmodic contractions, each persisting in the order of their succession. Stiffness is first experienced about the root of the tongue, which is usually retracted. Articulation therefore is imperfect. A sense of painful rigidity in the posterior muscles of the neck, and some difficulty in moving the jaw, are soon experienced. If the jaw be fixed, and tetanus proceeds no further, it is known by the name of *trismus*, or lock-jaw. Generally speaking, other sets of muscles become involved. The facial muscles are convulsed; the angles of the mouth being drawn up, presenting a peculiar expression, the “tetanic grin” *risus sardonicus*. Deglutition is accomplished with great difficulty, and fluids are convulsively ejected when any attempt is made to swallow them. In this particular, tetanus resembles hydrophobia. Even the sight of fluids may occasion dread,—another point of resemblance. Yet in no other respect is there any similarity between these diseases. No foaming at the mouth of a thick mucus, with constant movement of the jaw to extricate it, is ever witnessed, as in hydrophobia. Other peculiarities supervene. Pain strikes through the body from the ensiform cartilage backwards to the spine, and being accompanied with intense spasm of the diaphragm, occasions agonizing dyspnoea, which has been compared to that of hydrophobia. Very soon the muscles of the back contract, and with such violence that the body is drawn into the form of an arch resting on the head and buttocks (*opisthotonos*); or the abdominal muscles contracting, become as hard as a table, and draw the body forward (*emprosthotonos*). During these spasms, the rectus muscle has been torn with the violence of its contractions. The body is sometimes bent to one side (*pleurosthotonos*). Next in order, the muscles of the lower extremities are involved; and lastly, those of the upper, excepting the fingers, which generally remain moveable to the last. The tongue also is rarely involved, although it may be thrust violently against the teeth and be much lacerated.

Such is the ordinary course of events in Tetanus. They constitute one continued manifestation of spinal excito-motion, without suspension of the cerebral functions; but, as would be expected, the tetanic spasms—violent and continuous—provoke general disturbance of the *organic* functions. Thus, the respiration being much embarrassed, the heart beats more quickly and forcibly, giving to the pulse similar characters;

but they are eventually succeeded by feebleness and irregularity. The urine is perhaps scanty and high-coloured, and is sometimes retained or voided in small quantities, while the skin pours forth abundantly a sour-smelling sweat. Lastly, obstinate constipation is a constant and significant symptom throughout this disease; and should an evacuation occur, it is singularly offensive. "I remember," says Abernethy, "on one occasion, asking an old nurse what sort of evacuations had come from a tetanic patient, who for a week had no relief from the bowels; 'Lord, sir,' she replied, 'they are not stools, they are sloughs.'"

The *diagnosis* of tetanus is not always clear. I have already noticed how it differs from hydrophobia, epilepsy, apoplexy, and hysteria. But it may resemble the latter disease. *Hysteria* with spasm.—Hysterical tetanus may occur in females, and present a wonderful likeness. No fatal case is recorded. According to Dr. Copland; in females, trismus or subacute tetanus may assume an hysterical character, or hysterical symptoms may be associated with the tetanic, the disease being really tetanus and occasioned by an injury. Certain *drugs* produce convulsions, resembling those of tetanus. *Strychnia*, is thus specially deceptive. But the tetanic spasms, produced by strychnia, are remittent or intermittent, and subside entirely as the poisonous influence passes off, or kill in the first onset if the dose or doses be sufficiently potent. All these points of distinction were observable in the case of Cook, and were successfully urged against Palmer in the celebrated trial for the murder of that man. *Morphia* sometimes produces convulsions, but they are epileptiform, and long in their development.

**VARIETIES.**—Sometimes trismus and general tetanic twitches supervene on continued prostration, and remaining associated with it, constitute a variety of "*prostration with excitement*." The excitement is *tetanic*. Such were the phenomena I observed during the course of a severe burn, under the care of Dr. A. Marsden in the Royal Free Hospital. The burn extended over the toes and instep of the right foot and lower part of the leg. Its depth was to Dupuytren's fifth degree. The annular ligament was destroyed, the interior of the ankle-joint exposed, as also were the carpal bones, and the nails were burnt away. An attempt was made to save this foot, which would, I believe, have proved successful, with the removal of portions of bone; but the patient, a middle-aged woman, was fat and flabby, and a hard drinker. Prostration continued, and in a few days partial trismus, with tetanic twitches of the arms and hands, set in. The patient's mind wandered; she frequently raised her head, uttered a few words, and then dropped on to the pillow, turning her eyes right and left with restless agitation. I suggested to Dr. Marsden, who was good enough to ask my opinion, that amputation might be deferred, and that a grain of opium, with ten grains of castor, be given every four hours. The trismus never became complete, nor the tetanic twitches more general; but this condition lasted for more than a week, with continued prostration, when the woman died exhausted.

In other cases of continued irritation *pure* tetanus supervenes. A man died of universal tetanus in a few hours after an oblique fracture of the thigh-bone, which penetrating the rectus muscle, was continually playing through the belly with a see-saw\* motion. A man having a simple fracture of the femur, and who appeared to be doing well for four days, was seized on a sudden with lock-jaw, and died in three days of acute

\* Constitutional Irritation. A further Inquiry, 1835. Travers, p. 292.

universal tetanus. Examination showed that the upper fragment of the bone, obliquely fractured, had perforated and left a detached spiculum of considerable size transfixing the vastus internus muscle.\*

Certain varieties are noticed by Mr. A. Poland, in his elaborate article on Tetanus.† *Spasms primarily attacking the muscles of the part injured*, instead of the muscles of the jaw. Two cases are mentioned, both of which were fatal. In the one, two months elapsed, before the first symptoms occurred, a neuralgic affection of the muscles of the ball of the thumb, without any appearance of inflammation. The injury, originally, was a lacerated wound of the fleshy part of the thumb, by a splinter of teak-wood, which had transfixed the part. This was withdrawn at the time, and the wound healed soundly. But, after death, two pieces of splintered teak were found imbedded in the abductor muscle, and resting on a branch of the radial nerve. The other case, was occasioned by a blow of a schoolmaster's cane on the hand. In this instance, both pain and spasm commenced in the injured part; followed by a gradual spasmodic contraction of the flexor muscles of the hand, drawing the fingers into the palm, and subsequently extending to the arm and other parts. *Absence of pain* was characteristic of one case, even to the last moment of existence. The cramps were accompanied by a tingling and agreeable sensation, with a strong tendency to laughter. *Special affection of the muscles of the face and eye*, was noticed in three cases, simulating ptosis in two of them. The muscles of the eye are sometimes affected; the eye-ball being fixed and drawn slightly inwards. The pupil may be contracted or dilated. *Cerebral complications* are very rare; but delirium may supervene towards the close of tetanus. *Epilepsy* is another quite exceptional complication, in a patient subject to this disease. Screaming and convulsions, apparently not epileptiform, may occur. *Motor-paralysis* occurred in two cases of the seventy-two, in Guy's Hospital, from which the above results were gathered. *Remission of the symptoms* is extremely rare, yet it has been noticed in several instances. In one case—according to Dupuytren—tetanus subsided for twenty-eight days, and then returned after an exposure to cold.

All these anomalous forms of tetanus are worthy of notice, as bearing on the, possibly obscure, diagnosis of this disease.

*Pathology.*—Until recently, the pathological anatomy and interpretation of the functional or pathological phenomena of tetanus, were involved in great obscurity. And although the essential nature of this disease may yet require further elucidation, and especially by a more extensive assortment of *post mortem* examinations; the original researches of Mr. Lockhart Clarke‡ have brought to light a series of structural changes in the spinal cord, which are of the highest importance.

In six cases, these changes may be summarily stated as follow; and, apparently, in the following order of succession.

No morbid deposit nor any appreciable alteration of structure takes place in the walls of the blood-vessels of the cord; but the arteries are frequently dilated at short intervals, and, surrounded, sometimes to a depth of double their diameter, by granular and other exudations; beyond and amongst which, the nerve-tissue, to a greater or less extent has undergone certain changes. In the first stage, softening of this

\* Constitutional Irritation. A further Inquiry, 1835. Travers, p. 315.

† System of Surgery. Ed. by T. Holmes.

‡ On the Pathology of Tetanus, 1865: Med.-Chir.-Trans. Lond.

tissue; secondarily, granular disintegration, the tissue becoming softer or semifluid, and more transparent. Ultimately, the reduction of the tissue to a fluid state. This fluid at first, is more or less granular, holding in suspension the fragments and particles of the disintegrated substances, but in many places, it is perfectly pellucid. The blood-vessels also share in the disintegration of the part, and commingle with their ensheathing granular exudation. Thus a general softening and disintegration of structure has taken place. A fluid area, of considerable size, may occur at a single spot, and extend to the surrounding tissue; or at several spots, which advancing, coalesce between irregular masses of the tissue, or portions separating, are left as islets in the fluid.

This process of destruction affects the grey substance of the cord; perhaps its central part.

The same lesions of the cord are found in paralysis. But they are commonly unaccompanied by *spasm*, during life. Tetanus therefore probably differs only from that disease in being associated with a morbid condition or injury of some of the peripheral nerves. A marked congestion and inflammation of a nerve connected with, and leading from, a wound that has occasioned the disease, is a local morbid condition, which Mr. Erichsen states he has never found wanting; the vascularity, which may be very intense, often extending up the neurilemma to a considerable distance.

It would therefore appear—observes Mr. Lockhart Clarke—that this condition or injury of the peripheral nerves is the determining cause of the phenomena, and that the spasms of tetanus depend on the conjoint operation of two separate causes.

First, on an abnormally excitable state of the *grey nerve-tissue of the cord*, induced by the hyperæmic and morbid state of its blood-vessels, with the exudations and disintegrations resulting therefrom. This state of the cord may be either an extension of a similar state along the injured nerves from the periphery, or may result from reflex action on its blood-vessels excited by those nerves. Secondly, the spasms depend on the persistent irritation of the *peripheral nerves*, by which the exalted excitability of the cord is aroused; and thus the cause which at first induced in the cord its morbid susceptibility to reflex action is the same which is subsequently the source of that irritation by which the reflex action is excited.

In so-called *idiopathic* tetanus, arising from exposure to cold and damp, it is probable that the morbid condition of the blood-vessels of the cord, results from changes in the state of the peripheral nerves, which may act through reflex action or otherwise.

Associated with these essential changes of structural condition in tetanus, others which are apparently incidental, may be noticed. A marked vascularity of the membranes of the cord and engorgement of the veins within the vertebral canal. In a case of strangulated femoral hernia, for which I operated, all went on favourably for a week, and the incision had nearly healed; when suddenly the most violent tetanus set in, beginning with locked-jaw, proceeding to appalling opisthotonos, and terminating fatally on the fourth day, by which time the wound had reopened and become gangrenous. I carefully examined the cerebro-spinal axis throughout its whole extent. The intra-spinal veins were gorged with blood, but not those of the cord itself. The intestines have been found much inflamed in several cases; and in two, a yellow, waxy fluid,

of a peculiar offensive odour, covered their internal surface.\* The pharynx and œsophagus may be much contracted, and contain a viscid reddish mucus.† The muscles are usually rigid; sometimes ruptured, and sometimes there is no rigidity.

*Causes.*—*Injuries* of all kinds may possibly be followed by tetanus. From the most trifling scratch to the most terrible laceration, tetanus may ensue, yet not with equal probability. But it occurs most frequently from those injuries which in point of their *extent* or *persistence*, by continued nervous irritation, are most conducive to the continuance of Shock. I have already noticed that variety of “prostration with excitement,” in which the excitement is tetanic. Burns are thus peculiarly liable to induce tetanus. Punctured, lacerated, and contused wounds, particularly of the hand or thumb, of the sole of the foot or of the toes, have a direct tetanic tendency. Unyielding fibrous textures are peculiarly revengeful in this respect. Compound fractures and dislocations, rather than the simple form of these lesions, are threatening complications; and more so, if the fracture be oblique and playful among nerves and muscles, or if the dislocation be that of a ginglymoid joint, as the thumb. Gunshot wounds, involving possibly other forms of injury, rank high as causes. Amputation, as in the thigh, or the removal of a breast or testicle, are known causes. So also minor operations; *e.g.*, for fistula in ano, ligature of piles, extraction of a tooth, cupping, the irritation of a seton. *Diseases*; *e.g.*, gangrene, ulcer of the leg, a guinea worm under the integument, caries of the tibia. In obstetric practice; abortion, retained placenta.

The *condition* of a wound, at the time of tetanus, seems to have little relation to the disease. Thus, in one case, recorded by Hennen, cicatrization was completed on the same day that life terminated; and Dr. Elliotson observes, that the disease has sometimes declined and ceased, although the wound daily grew worse.

*Period of probation* or incubation, between the local injury and the commencement of tetanus. This period has its *average* limits of duration. As extremes may be mentioned a few hours, or some days,—the fifth to the fifteenth day, and up to the twenty-second day; the average being the tenth day.

Tetanus arising from any of the foregoing forms of Injury, is denominated *traumatic*; as distinguished from tetanus arising from other causes, whether external or internal, unconnected with Injury, the disease being then named *idiopathic*. But this distinction relates to origin only, and is, moreover, not always definite. Such causes include, exposure to cold and damp, currents of air hot or cold, bad ventilation or atmospheric poisons, irritation of worms, sudden suppression of the perspiration, of the catamenial or lochial discharges, or of acute diseases, and terror or anxiety of mind.

*Predisposing causes.*—The disproportion, in many cases, between the local injury and the development of tetanus, as well as the varying period of probation intervening; are probably due to the influence of predisposition. A scratch of the thumb by a broken plate, proved fatal in a quarter of an hour; and in other cases, a slight blow, as by a whip-lash under the eye, although the skin was unbroken, has been followed by tetanus. In such cases, some predisposing condition probably was

\* Med.-Chir.-Trans., vol. vii. p. 475.

† Mém. de Chir. Militaire. Larrey, t. iii. p. 287.

also in operation. *Age*.—No period of life is exempt; but, perhaps, infancy and middle age are most subject. In infants, the disease—then named *trismus nascentium*—occurs from seven to fourteen days after birth. It may terminate fatally in ten or thirty hours, or life be prolonged to eight or nine days. Its origin is apparently traumatic; namely, from division of the umbilical cord, or irritation of the intestines by meconium, or worms; or it has been traced to unwholesome food, bad ventilation, or exposure to currents of air. It occurs very frequently in the Tropics, occasionally in Europe. *Sex*.—Males are most liable to tetanus, in a ratio of about seven to one female. *Habits of life* seem to have little influence, the disease attacking equally the temperate and the intemperate. *Constitutional susceptibility* is not apparent; individuals of any temperament being equally liable. *Climate*.—The disease is more prevalent in warm climates and in marshy districts; also near the sea-coast than inland. Nevertheless, *season of the year* is said to have no influence on the occurrence, or the mortality, of tetanus.\*

*Course, and Terminations*.—(1) Generally, tetanus proceeds in a continuous course of development; affecting the muscular system, in the order already mentioned, and terminates *fatally*. About the second or third day, as *acute* tetanus; the ninth or tenth day, as *chronic* tetanus. But the former is commonly fatal, the latter far less so. The *mode of death*, is, commonly, during a *paroxysm* affecting chiefly the muscles of the larynx; which, by complete closure of the glottis, produce almost instant suffocation. The slightest attempt to move, or to swallow, seems to excite this issue. I witnessed it in one case, during the attempt to swallow an opiate pill. A sudden jerk of the throat occurred, a suffusion of the face, succeeded by deadly pallor, and all was over. *Exhaustion*, is another, but less frequent mode of death.

(2) *Recovery* is preceded by a gradual subsidence of the tetanic contractions; and this happy issue is generally granted to the few who survive the tenth day. It is also stated, that the longer the period of *probation*, before the commencement of tetanus, the greater is the probability of recovery. Conversely, the shorter the period of probation, as well as the more rapid the progress of the disease, the more surely fatal is the issue. But this, perhaps, general rule, is exceptional in many cases of rapid progress, after the probationary period of ten days.

*Prognosis*.—The prognosis of tetanus will be guided by a due consideration of the conditions which chiefly determine its tendency to a fatal issue, or to recovery. They are, principally, the traumatic or idiopathic origin of the disease, the influence of predisposition, as evinced by its speedy accession, and its acute or chronic progress.

*Treatment*.—*Preventive measures* are the most, or only, effectual resources. This implies the early detection and removal of any persistent causes in operation; such intervention necessarily having reference to local causes, rather than to constitutional causes, which mostly elude detection or are beyond control. Hence prevention is practicable mostly in tetanus of *traumatic* origin. Happily, also, the intervening period of probation is available for surgical interference. Wounds may be thoroughly cleansed of foreign bodies, and the parts adjusted. Swelling, under tight, unyielding textures, may be relieved by incisions. Burnt surfaces may be effectually protected from the influence of the air. Most compound

\* Guy's Hospital Reports, vol. iii. ser. iii.

fractures and dislocations can be soon detected, reduced and kept in position.

Are there any other causes possibly in operation besides the local injury? Constipation is constant and significant; significant, partly because constant, and also because of the peculiar matter voided when an evacuation does occur. More than forty years since, Abernethy proposed for the consideration of surgeons this question—whether the disordered condition of the digestive organs, established during the irritative state of the wound, may not be the occasion of tetanus, when that irritation has itself ceased? If, he adds, this proposition be established the very important conclusion follows, that by preventing the disordered condition of the digestive organs, you would prevent tetanus. No purgative medicines that I know of for this purpose are specially serviceable.

The foregoing preventive considerations are most important; for every practical surgeon will concur in acknowledging the hopelessness of all known medicinal treatment when the disease is fully developed; and, in such case, the equal inutility of any surgical operation to relieve the symptoms of, much more to cure, this deadly disease.

*Remedies*, then, there are none, at present known. The long list of medicinal and surgical resources which have been successively tried, and have failed, Mr. Poland thus enumerates. Antiphlogistics, including blood-letting, purgatives, calomel, antimony, colchicum, &c., have been extensively used; alteratives, as the various preparations of mercury, large doses of fixed alkalies, solutions of arsenic, &c.; diuretics, in the form of tincture of cantharides, oil or spirits of turpentine, given in frequent and large doses, so as to irritate the urinary passages, or to occasion bloody urine; sedatives, such as digitalis, tobacco, nicotina, hydrocyanic acid, aconitina; anodynes and narcotics, as opium, morphia, belladonna, cannabis indica, ether and chloroform internally and by inhalation; stimulants and antispasmodics, including musk, ammoniacum, camphor, turpentine, assafœtida, castor, wine and other stimulants; tonics, such as quinine, bark, strychnia, iron, zinc, &c.; hygienics and dietetics, as support, milk-diet, &c.; injections into the veins of solutions of opium, stramonium, &c.; tracheotomy and laryngotomy.

This list of variously accredited remedies, is at least suggestive of what to avoid, as useless, or perchance, noxious, in the course of tetanus. Chloroform may relax the spasms, for a while, and thus relieve pain. It had this temporarily palliative influence in the overwhelming case, after strangulated femoral hernia, which I had reduced by operation.

#### CHAPTER XIV.

WOUNDS:—INCISED WOUND. WOUNDS OF ARTERIES AND VEINS.

A WOUND is a solution or breach of continuity of the soft tissues, suddenly produced, in any part of the body. Such lesion may be effected by various instruments of a cutting, tearing, or puncturing, character. Hence, Wounds are commonly distinguished, as Incised, Contused and Lacerated, and Punctured. Gun-shot Wounds are also contused and lacerated. Poisoned wound is characterized, not by the nature, and still less by the extent, of the lesion itself, which may be only a slight puncture; but, by the accompanying introduction of some poisonous matter, whereby the constitutional disturbance becomes of far greater consequence than the local lesion. Such are stings of bees, wasps, hornets; snake-bites; bites of rabid animals, giving rise to hydrophobia; and dissection wounds.

Excluding, therefore, poisoned wounds; Wounds differ most significantly in their relation to the laws of Reparation. *Incised* wound has a natural *tendency* to undergo repair, or to heal, by primary adhesion, when its surfaces are placed in contact; all other wounds, in proportion as they are *contused* or *lacerated*, have a natural *tendency* to sloughing, and then to undergo repair by the slower process, on an open surface, of suppurative granulation and cicatrization.

#### INCISED WOUND.

An Incised Wound is a solution of continuity of the soft textures; suddenly produced, and with even division of the tissues. The former character distinguishes this lesion from a breach resulting from ulceration; the latter character defines it from a contused wound.

*Symptoms.*—Pain, and hæmorrhage or effusion of blood, in various degrees, accompany the division of nerves and blood-vessels; and the wound opens or gapes more or less, according to the elasticity, muscular contractility, and weight of the parts. The former symptoms are not peculiar to this, or any other kind of Injury,—thus illustrating the insufficiency of

Functional Symptoms in Diagnosis [P. p. 169]; while absence of the latter symptom—gaping of the wound—is the negative distinction of a *subcutaneous* incised wound. But this lesion is, moreover, not exposed to the action of the air; a peculiarity of essential importance—as determining the course of a subcutaneous wound in respect to its more speedy reparation.

*Cause, and Effects of Incised Wound.*—Incised wound is produced by the edge of any sharp cutting instrument, as a knife; not by a blunt or a pointed weapon.

Its effects are essentially local, in relation to the function of the part wounded; but the lesion produces constitutional disturbance in proportion to the implication of nerves and blood-vessels, and to the functional importance of the part in the system. Hence, the *Shock* of injury to the nervous system; the *Collapse* arising from profuse or persistent hæmorrhage; and the serious *functional disturbance* arising from wound of an internal organ, as the lung or intestine.

*Reparation.*—Incised wound tends to undergo the reparative process of healing by primary adhesion, unaccompanied by inflammation; when the surfaces of the wound are in contact. But an incised wound may heal by other modes of reparation, under different circumstances. It will therefore be necessary to here describe all these modes of healing, which are four in number; although the latter two will be found to pertain more especially to Contused and Lacerated, or open, Wounds. The inherent power of organization which the *materials* for reparation, possess, must first be noticed; and in virtue of which all other kinds of Injury undergo repair.

*Reparative Materials.*—*Coagulable lymph*, and, possibly, *blood* are the materials supplied; and their reparative power is exhibited by the organization they both undergo, spontaneously. John Hunter, so far as I know, first advocated the possibility of blood undergoing this change; and it was with him the mode of “union by the first intention.”\* Subsequently, the organizability of blood was disputed by Mr. Travers† and other observers. Now, however, it is amply confirmed by the microscopic observations of Zwicky,‡ Paget,§ and Dr. W. T. Gairdner,|| not to mention others. I allude to observations such as these:—the organization of blood effused in serous sacs, particularly in the arachnoid; of clots in veins being converted into fibrous cords, or having evinced less constructive power, degenerating into phleboliths; clots forming distinct tumours in the heart and arteries; and the clot above a ligature on an artery becoming part of the fibrous cord which constitutes the impervious portion of artery.

Mr. Paget thus estimates the function of blood in the repair of injuries:—1. It is neither necessary nor advantageous to any mode of healing. 2. A large clot, at all exposed to the air, irritates and is ejected. 3. In more favourable conditions, the effused blood becomes enclosed in the accumulating reparative material; and while this is organizing, the blood is absorbed. Lastly, it is probable that the blood may be organized and form part of the reparative material; but even in this case it probably retards the healing of the injury.

\* Blood. Inflammation and Gun-shot Wounds, p. 193-4.

† Physiology of Inflammation, and the Healing Process, 1844, p. 162.

‡ Die Metamorphose des Thrombus, 1845.

§ Surgical Pathology, vol. i. 1853, p. 174.

|| Edinburgh Monthly Journal, Oct. 1851, p. 392.

Mr. Paget then traces the process of organization which coagulable lymph undergoes. Fibro-cellular or connective tissue is formed, but in either of two different ways, or by both processes of development simultaneously; and the particular mode of lymph-development is determined chiefly by the circumstance of exposure or not to the air. Lymph effused for the repair of open wounds generally develops itself into fibro-cellular tissue, through nucleated cells, which elongate into filaments; while that effused for the repair of subcutaneous wounds as generally develops itself into this tissue, through the medium of nucleated blastema—by the nuclei developing themselves into fibres (Henle), or by the blastema itself undergoing fibrous transformation (Paget). The same state of organization—fibrous tissue—is thus attained, by either of these different processes of self-development, or, as I have said, by the association of both in some, probably many, instances of reparation.

*Modes of Reparation.*—Wounds may heal in one or other of four different ways, first clearly distinguished by Macartney; and subject to certain modifications, the distinctions he drew are still accurate.

First. Immediate union, without any intervening substance, such as blood or lymph. (Union by the first intention, and through the medium of blood—Hunter.)

Secondly. Union by the medium of coagulable lymph, or a clot of blood—mediate by lymph or blood. (Union by adhesion, or adhesive inflammation—Hunter. Union by first intention, as now commonly understood. Primary adhesion—Paget.)

Thirdly. Reparation by suppurative granulations.

Fourthly. Healing under a scab. (The modelling process of Macartney?)

Each of these processes of healing claims some further notice, and in reference to the power of reparation indicated thereby.

(1) *Immediate union* is effected only under certain circumstances. Incised wounds will thus unite when the cut surfaces are immediately replaced in close contact, so that no substance of any kind intervenes. The blood itself is pressed out of the wound, the divided blood-vessels and nerves are brought into perfect contact, and reunion ensues by the opposed surfaces simply growing together. This process of repair is very speedy. It will take place in two or three days; possibly in almost as few hours. No intermediate substance exists in a wound thus healed; consequently no cicatrix or mark remains. Nature undertakes and may accomplish the immediate union of any incised wound, irrespective of its extent, provided only the conditions mentioned are fulfilled. Thus, divided nerves may reunite, as manifested by the recovery of sensation or other function peculiar to them. But restoration is, generally, very slowly effected. In a case under my care at the Hospital, the tongue was severed by an incised wound, extending nearly through the substance of that organ, which hung by a mere shred on the left side; dividing the gustatory and hypoglossal nerves on both sides. The divided portion having been promptly replaced and secured, in even contact with the root, complete reunion took place;—the tongue slowly recovering the power of motion and the sense of taste.

(2) *Primary Adhesion.*—A period of reparative inactivity, perhaps of short duration, succeeds the injury; during which the divided textures are indisposed to unite, although placed in apposition. But this condition of apparent inactivity may partly be due to interception of the

process of reparation; either by the presence of some foreign body between the cut surfaces, or from continued hæmorrhage. The process begins whenever the textures are *glazed* over, thus sealing the blood-vessels. This appearance of the wound denotes either the previous exudation of reparative lymph, or the coagulation of a thin layer of blood, just sufficient for adhesion. Reparation then commences. Either form of reparative material—lymph or blood in small quantity—undergoes organization, apparently by virtue of its own inherent formative power.

*Fibro-cellular tissue* thus produced, consists of cells lengthened and attenuated into fibres. (See Fig. 2.) This constitutes an intervening layer of texture as the permanent bond of union, thence named connective tissue, and which presents externally the appearance of a linear cicatrix, or scar. Fibres of this kind must not be confounded with the very fine filaments seen in *coagulated lymph*, and which are produced apparently by the linear coalescence of molecules. (See Fig. 1.) The one are cell-fibres, and arranged when finished as fibro-cellular tissue, in fibres having cellular interspaces; the other are molecular fibres, and interwoven like felt in various directions, as seen in the clot of buffed and sized blood, or in coagulated lymph exudation on the surface of a serous membrane. (See Fig. 1.) These fibres are, however, accompanied with numerous cells, each containing three to eight granules; and similar cells are found in reparative lymph, in which they abound. Hence named *plastic cells* by Dr. Hughes Bennett, they are the *pyoid* cells of Lebert, so named from their general resemblance to pus corpuscles. But, unlike them, neither water nor acetic acid much affect plastic cells. New capillary blood-vessels shoot through the connective tissue; they are formed also in coagulated lymph, and occasionally in blood-clot, as reparative materials. These vessels are produced by a highly interesting process of development, as described with that of Healing by Suppurative Granulation, in Contused and Lacerated Wounds. Eventually, the new tissue is fashioned off, so as outwardly to resemble the particular texture in the substance of which it is interposed; but this resemblance scarcely extends to their minute structure. Reproduction of the original texture is, in fact, a rare event. Skin, with its papillæ and cuticle, muscle, tendon, artery, cartilage, and bone, in the first stage of fracture-union are severally represented by fibro-cellular tissue, more or less vascular; nerve is said to be repaired in like manner, and also by the formation of new nerve fibres, which running through the connective tissue, become continuous with those in the nerve above and below, thus reinstating its continuity. The grey matter of nerve centres would not appear to be reproducible.

This mode of union is less desirable than the immediate; the formation of lymph or exudation cells being a process so indefinitely separated from that of pus-cells, that union thereby is much more likely to pass into suppuration than any process in which no lymph is formed; then again, it is probably not so speedy in most cases; and finally, if accomplished, it is not so close, a scar therefore always remaining by the organization of the new intervening substance.

(3) *Suppurative granulation* and *cicatrization* is that process by which all other than incised wounds are commonly healed. It will be described most advantageously in connexion with Contused and Lacerated Wounds.

(4) *Healing under a scab* ranks higher, in respect of its result, than that by suppurative granulation. Open wounds, and superficial burns,

may heal in either way. The cicatrix formed under a scab more nearly resembles the natural textures, and being also less contractile, is less disfiguring. Yet the process of healing in this way is more liable to miscarry. Inflammation is apt to supervene, and discharge accumulating under the scab, the healing process is again and again delayed, or recommenced. No such impediment interrupts the progress of suppurative granulation, or the course of an *open* sore.

The scab itself is formed of dried blood, lymph, or pus; but the precise nature of the reparative process underneath is concealed from our view. So far—observes Mr. Paget—as one can discern with the naked eye, the wounded surface forms only a thin layer of cuticle on itself; no granulations, no new fibro-cellular tissue, appear to be formed; the raw surface merely skins over, and it seems to do so uniformly, not by the progressive formation of cuticle from the circumference towards the centre, as is usual in open wounds.

Healing by the “modelling process” is somewhat similar. It takes place under a scab or protective film. But that “natural growth” of textures proper to the part, by which it was said to be re-made or remodelled, and which was thought to be the special and characteristic feature of the modelling process, is probably only the growth of granulations, *without* suppuration, because not exposed to the air.

This mode of healing, like the last, is often witnessed in the wounds of animals. Macartney first described its characters, and I state them on his authority.

“The pain arising from the injury soon ceases. No tumefaction ensues, separating the edges of the wound; and its surfaces are not only disposed to lie in contact, but even to approach each other so much, that they cannot be kept asunder by mechanic restraint; there is therefore no necessity for the effusion of lymph; and as there is no cavity to be filled up, granulations are not formed. The surfaces of the wound, although they come into contact, do not unite by vessels shooting across; they are smooth, red, and moistened with a fluid, which is probably serum, and present the appearance of one of the natural mucous surfaces of the body. If any parts have been killed by the injury, they are detached by simply as much interstitial absorption as may be sufficient to set them free. The wound is finally healed by the same means which determine the shape of the natural parts of the body. It gradually diminishes in extent until obliterated; or it may be cicatrized before the surfaces are abolished, after which the same process of natural growth goes on until no part of the original wound remains. The cicatrix which succeeds the cure of injury by this modelling, or growing process, is small, pliant, free from callous adhesions to the parts underneath, and morbid sensations, that so often belong to cicatrices, which have for their bases deposits of lymph, or the new-formed structures, called granulation.

“When the modelling process, or cure by natural growth, goes on perfectly, there is no inflammation in the part, and the patients are so entirely free from all uneasy sensations, that I have known instances of their being ignorant of the real site and extent of the injury until they had examined the part with their hand, or seen it in a looking-glass.

“It might be anticipated, that as this mode of reparation bears so strong a resemblance to the natural formation and development of parts, it is the slowest mode; but this is of little account when compared with

its great advantage in being unattended with pain, inflammation, and constitutional sympathy, and leaving behind it the best description of cicatrix. It constitutes the nearest approach, in the higher classes of animals, to the regenerative power exhibited by some of the inferior tribes.”\*

The *Prognosis* of incised wound—as an adhering wound—is most favourable. But the breach of continuity may be maintained by various circumstances which prevent or impede coaptation of the parts. The *weight* and *mobility* of loose and pendulous parts, tend to prevent union, or to disunite them in the process of healing by primary adhesion. *Muscular action*, tending to displacement, will have the same effect, and to a greater degree, if co-operative. A deep and extensive flesh-wound, say of the thigh, illustrates this concurrence of causes. Any *foreign body*—e.g., grit, or clot of blood—intervening between the surfaces, otherwise in apposition, will prevent complete union, and tend to induce suppuration with an open wound.

These various conditions illustrate the Prognostic guidance of Persistent Causes. [P. p. 701.] But the surfaces of an incised wound are usually clean.

*Treatment*.—To be effectual, in regard to this or any other lesion, surgical appliances must meet the requirements of the natural process of reparation, throughout its course; of which the treatment will then be a continued reflection.

The Indications are three :—(1) Arrest of hæmorrhage; (2) removal of foreign bodies; (3) coaptation of the opposed surfaces.

*Hæmorrhage*.—Small vessels soon spontaneously cease to bleed; their cut extremities retracting and contracting. Larger-sized arteries bleed *per saltum*, in jetting streams of florid red blood. Venous hæmorrhage is distinguished by the even flow of purple or black blood. The treatment of hæmorrhage will be described in connexion with Wounds of Arteries and Veins. But the arrest of hæmorrhage, spontaneously, will be aided by exposure of the wound to cool air, or a stream of cold water squeezed from a sponge. Gentle pressure with the sponge on the cut surfaces will readily discover whether there be still any oozing from the bleeding points.

Obviously, any *foreign body*, if present, should be at once removed. Not roughly, however. The same application of water, as for hæmorrhage, will generally suffice to dislodge and carry away grit, &c., or the particles may be lightly brushed off with the wet sponge.

*Coaptation*.—The coaptation of an incised wound might be postponed, until the wound has become glazed and adhesive. Then reparative material begins to exude. This indication as to *time* was always observed by Mr. Liston, with regard to the amputation-wound of a limb, and all other *large* wounds. The deeper and more extensive the wound, the more advisable is it to wait this event; with one exception,—a deep muscular wound, which retracting and gaping, non-interference would allow the muscles to become agglutinated within their sheathing fasciæ. But the *general* rule—applicable alike to small cuts, or to extensive and deep incisions, accidental or surgical, is this;—hæmorrhage having ceased or been arrested, and any foreign body, accidentally present, having been removed; the wound is now prepared to undergo the process of reparation.

\* Inflammation, pp. 53-4.

(1) *Coaptation* signifies the adjustment of the apposed surfaces in even contact. This, however, implies a suitable position of the part, to relax any muscular action or tension.

(2) *Retentive Appliances.—Dressing.*—The maintenance of coaptation during the process of adhesion, also implies the same attention to position; and some kind of retentive appliance; both being necessary to insure rest. In the selection of any such appliance; the plastic nature of the healing process would indicate, that the less retentive it is, the better; provided only it be sufficient to maintain easy apposition. The surgeon should always consider his mechanical dressings in this light; that he may the more exactly reduce them to co-operative conformity with the course of reparation. And by clearly understanding the proper management of a typical form of Injury, which occurs so frequently in Surgical Practice, as does an incised wound, and which represents nine-tenths of surgical operations; he will be enabled to take a commanding view of his art.

The appliances in question are designed to maintain the apposition of, either the *lips*, or the *surfaces*, of the wound. Plaster, sutures, or both, fulfil the one intention; a bandage, with or without light compresses, accomplish the other purpose.

The *plaster*, commonly used, is the adhesive—diachylon—plaster. Isinglass plaster, introduced by Mr. Liston, is, however, preferable. It is equally adhesive, quite unirritating, and transparent, so that the progress of healing can be watched from day to day. If common adhesive plaster be used, the remark of Professor Gross is of some practical importance. It should be cut in the direction of its length, the texture in breadth being more yielding; so that if cut in that direction, the plaster is apt to become loosened when heated by the skin. Any blood or dirt around the wound having been washed off, the surface is lightly wiped dry with a clean soft cloth. Blood remaining, it stiffens, tightens and irritates; nor can it be removed subsequently without an unwarrantable degree of handling and rubbing. Thus also, any hair on the part, is better cut off in the first instance. Strips of plaster, of length and breadth suitable to the size of the wound, are then applied; and most advantageously, by placing the first strip over the *centre*, and another on either side alternately, leaving intervals between them wherever the edges of the wound lie in even and easy apposition. Any oozing is thus allowed to escape, the more so from a deep wound.

*Sutures* are made of silk-twist; or metallic wire, of various kinds; gold, silver, iron, or lead. They are apt to induce inflammation and ulceration of the skin around each, as a centre. Silver-wire is, perhaps, less irritating than silk, which acts as a seton. A number of such sutures are, in effect, so many little setons, along the margin of a wound. The apparently greater tolerance of silver sutures, is witnessed after the operation of joint-excisions. Fine telegraph wire has been introduced into surgical practice by Mr. Clover. It consists of a fine copper-thread, coated with gutta-percha. This is soft, flexible, tough, and perfectly unirritating; it admits, therefore, of ready introduction and knotting as a suture, and it may be left in the tissues for ten or fourteen days, without inducing any suppuration or inflammation along its track. Sutures, of some kind, are necessary alone, or as adjuncts to strips of plaster, whenever the wounded part is liable to be disturbed; whether by muscular action, its own weight, or looseness. Such parts are the lips, tongue, soft palate, cheeks, nose, eyelids, ears; breasts, abdominal walls,

bowels, scrotum, and the integuments around joints. When used, sutures are applied *before* the retentive strips of plaster; and only to bring the margins of the wound together, here and there, forming the "interrupted" suture. (Fig. 31.) Commencing in the *centre* of the wound, in order to judge of the even adjustment of the rest of its extent, the first suture is inserted by means of a curved needle, armed with silk or wire. Then another is placed alternately on either side, and so on, from point to point; but only where necessary to secure apposition.

FIG. 31.

FIG. 32.

If silk be used, each suture is tied with a reef-knot; if wire-suture be used, a twist or two will secure it. In either case the ends are then snipped off short. As few sutures only, as may be requisite, should be inserted; for, besides their irritating character, coaptation can be efficiently maintained in the intervals between them by strips of plaster. (Fig. 32.)

Other forms of suture are employed in special kinds of incised wounds.

The "twisted" suture is a waxed thread, twisted or coiled into a figure of 8 shape around a fine needle, previously transfixed through the lips of a wound in apposition. (Fig. 33.) It is most serviceable for wounds of the lips, as in the operation for hare-lip, and for wounds of the abdominal walls.

FIG. 33.

The "quilled" suture consists of a number of interrupted sutures, secured, not across the lips of the wound, but, on either side, to a quill, piece of bougie

FIG. 34.

or other small cylinder, placed parallel about half an inch from the margins of the wound. (Fig. 34.) Textures below the surface are thus approximated and steadily held together; an advantage in respect to a deep wound, as well as in any moveable part. Ruptured perinæum is thus secured. The "uninterrupted" suture, or Glover's stitch, is seldom used, excepting for wounds of the intestine, which are

stitched close so as, if possible, to prevent the escape of fecal matter. The "button" suture of Bozeman, the "clamp," and the "serrefine," of M. Vidal, may be here mentioned.

A *bandage* or roller, and *compresses* or light pads of lint, may be required to maintain the *surfaces* of a wound in contact. This, more especially, if the parts are muscular and liable to retraction, or bulky and apt to fall asunder. Deep or excavated wounds, therefore, mostly need this *extra* restraint or support. But it should be applied evenly, and only with sufficient pressure to invite adhesion, by preventing displacement and any oozing hæmorrhage. Amputation-wounds well illustrate the circumstances alluded to. Muscular retraction and weight of the flaps, thence recurring displacement and oozing hæmorrhage, are overcome and obviated, by the additional retention of compresses and a bandage applied with even and moderate pressure.

The line of incision, visible between the strips of plaster, needs only the protection of a piece of wet lint, as "water-dressing," covered with oil-silk to retard evaporation; and which may be occasionally moistened without removing it or otherwise disturbing the healing process. *Collodion* is sometimes used for the purpose of temporarily sealing the lips of an incised wound. Applied with a camel's-hair brush; it should be used quickly, and in such quantity that one application of the brush may suffice; for collodion is very adhesive, dries almost immediately, and contracts.

*Antiseptic-Dressings.*—Disinfection and Deodorization have, of late years, attracted much attention, more particularly in this country; and especially in the treatment or dressing of Wounds, whether occasioned by accident or by surgical operation. These terms, disinfection and deodorization, are not at all necessarily synonymous. Disinfection represents the neutralization or destruction of the infectious property, whatever that may be, in the atmosphere, or in any liquid, or solid substance, as an article of clothing—whereby a disease, itself infectious, is communicated and propagated; Deodorization signifies only the neutralization of an odoriferous property, and possibly, simply by masking it by some more powerful and penetrating odour. Probably, disinfection is far more frequently attended with deodorization, than the latter implies the former. Thus, solutions of carbolic acid, chlorine, and chloride of zinc, are Disinfectants; whereas, the aroma wafted from burning spices, or the fragrant spices of the East, employed in times gone by, would sweeten rather than purify the sick chamber; like the camphor-bag in domestic use, or the time-honoured rue strewed about the dock of our criminal courts—all such agents more often delude the sense only—they are Deodorizers. In relation to Infectious Fevers—diseases which equally concern the Surgeon and Physician, the prevention of Infection and its propagation, is fully considered in my other work. [P. Ch. viii.]

Disinfection in relation to the treatment of Wounds—accidental or surgical, may be termed Antiseptic; the object being to prevent the putrefaction of any blood or liquor sanguinis extravasated, or of pus formed subsequently—and it would seem to also control the formation of the latter fluid. Thence, primary union of the wound is induced, and the liability to purulent infection of the blood—Pyæmia, or by decomposing animal matter, septic matter, producing Septæmia, is prevented; the further liability of any propagation of infection being necessarily

excluded, as the wound remains healthy, and heals with little or no supuration.

The *principle* of antiseptic-treatment is twofold :—

Firstly. By the exclusion of air, as the infecting agent, from the wound.

Secondly. By the interposition of some positively disinfecting, or antiseptic dressing, in the form of a close covering to the wound. Professor Lister of Edinburgh—who has mainly originated antiseptic-treatment—enlarges this aspect of the principle, thus;—"an antiseptic to exclude putrefaction, with a protective to exclude the antiseptic, will by their joint action keep the wound free from abnormal stimulus."\*

This principle may be *fulfilled* as follows :—

(1) Exclusion of air from a wound may be effected by simple water-dressing, as already described; care being taken to apply the dressing so as to form a close covering, and which is enveloped in oiled-silk. Or, the air may be withdrawn by an exhausting receiver, as has been tried in France.

(2) Antiseptic-dressings of various kinds have been used; and as a process of treatment, comprising many details, apparently essential to its success as a specific method, this has been named by Professor Lister, the "Antiseptic system of Treatment."

(a) The "protective" should possess several properties; it should be a material impervious to carbolic acid, and unstimulating in its own substance; at the same time, it must be insoluble in discharges, and sufficiently supple to apply itself readily to the part. Various materials have been tried and discarded; as a metallic plate, itself impervious, but when made of block tin, it was too rigid, and tin-foil soon wears into holes. Gutta-percha soon transmits carbolic acid. The "protective" Lister now uses, is oiled silk; prepared by having a thin coating, brushed over it, of a mixture consisting of one part of dextrine, two parts of powdered starch, and sixteen parts of cold watery solution of carbolic acid—1 to 20.

(b) Antiseptic "lac-plaster" is laid evenly over the protective and extending freely beyond the wound; and over both, the part is enveloped with a cloth, to absorb any discharge which may ooze from beneath the margin of the impermeable plaster, the cloth being secured in position by a roller-bandage. The plaster now used is incorporated with a soft cloth, instead of being spread upon starched calico.† It is thus made more flexible and durable, but very thin; so that a double layer may be advisable, to double the store of acid in the application, when much discharge is anticipated, or when the dressing is not to be removed for some time. "The carbolic oil," and "carbolic paste or putty," formerly used and advocated by Mr. Lister, he now seems to have almost abandoned. Recently, however, to complete the antiseptic appliances which may be requisite in the treatment of wounds; he has devised "antiseptic ligatures" of prepared catgut, for securing blood-vessels, and "antiseptic sutures," for retaining the lips and surfaces of a wound in contact.

Previously, to applying the solid antiseptic dressing, above described, the wound is well syringed out with "carbolic solution or lotion," as strong as it can be made,—one part of the crystals to twenty of water. The

\* A Case of Compound Dislocation, &c., illustrating the Antiseptic System of Treatment. 1870.

† This plaster, in its best form, may be obtained from the Old Apothecaries' Company, Virginia Square, Glasgow.

transient irritant property of this strong solution, is said to be far less objectionable than the abiding influence of the more acrid products of putrefaction; even although the solution be thrown into the interior of a large joint, as in the dressing of a compound dislocation of the ankle-joint. A weaker lotion, one to forty, will suffice, in dressing a recent, and surgical, wound. The *skin* around a wound is well washed with the lotion. Then, the protective, lac-plaster, outer cloth and bandage, are severally applied.

*Reapplication* of the dressing may be required, or advisable, occasionally; in the intervals, the bandage and cloth may be daily moistened with carbolic solution, strong or weak,—one to eighty, to renew a supply of the antiseptic to the lac beneath. Great care must be taken in removing the antiseptic dressing, not to admit air into the wound, or any regurgitation of discharge. Hence two precautions; in removing the cloth, the plaster should be held down over the wound, so as not to be drawn up with it, at any part where they may have become adherent by dried discharge; then, in raising the plaster, the nozzle of a syringe is inserted beneath its margin, and a stream of carbolic solution is thrown over the wound, until a piece of calico soaked with the same lotion, has been placed upon it, as a temporary security, pending the reapplication of the plaster. “These details, while essential to success, are, happily, easy of execution.”

*Theory of the Antiseptic Treatment.*—To form an impartial judgment respecting the efficacy of “antiseptics,” it is necessary, as in all other aspects of surgery, to draw a sharp line of distinction between observed facts, and their supposed explanation or interpretation. The non-recognition of this obviously important distinction has influenced both favourably and unfavourably, the practice of antisepticism. To prevent, if possible, the putrefaction of animal matter, whether as blood or discharge, in contact with wounds, is known to be most important, pathologically, as an observed fact; and that carbolic acid has some such influence, is another observed fact. But, how it operates is doubtful. Opinions are divided, though not equally.

Omitting the small section of *disbelievers* in antiseptic treatment, the Profession generally, as *believers*, are divided respecting its *modus operandi*.

The *chemical* theorists attribute the putrefaction observed, to the decomposition induced by the oxygen of the air, a process of oxidation.

The *germ*-theorists attribute the putrefaction observed, to the production of living organisms developed from germs or ova floating in the atmosphere, as constituents of its dust; and not as the result of “spontaneous or equivocal generation,” in the putrifying animal matter.

The balance of *evidence* would seem to be in favour of the latter or germ-theory. The observations of Cagniard Latour, 1836, in the discovery of the yeast plant, followed by those of Schwann of Berlin, in the following year, and the subsequent discovery of minute, jointed, living bodies,—vibrios in putrid matter, supplied the basis of the germ-theory; while the well-known power of the atmosphere to carry and disseminate seeds or dust, completed the theory. The researches of Pasteur seem to have brought it to actual demonstration. Hence, antiseptic treatment would consist, in excluding the atmosphere from wounds, and in interposing some agent which shall destroy the germs in their introduction by any

exposure to the air. Has carbolic acid, or other so-called antiseptics, any such effect? The question is still *sub-judice*.

*Results.*—Comparing the aggregate results of amputations, in the Glasgow Royal Infirmary, Professor Lister finds the mortality to have been:—Before the antiseptic period, 16 deaths in 35 cases, or 1 death in every  $2\frac{1}{2}$  cases; whereas, during the antiseptic period, it was, 6 deaths in 40 cases, or 1 death in every  $6\frac{2}{3}$  cases. This is certainly a greatly diminished mortality, and its significance is more notable from the relative death-rate of amputations in the upper limb; where generally, neither the injuries nor the operations involve much loss of blood or shock to the system, so that if death occurs, it is commonly the result of the wound assuming an unhealthy character. There were 12 amputations in the upper limb, in each of the periods referred to. Of the 12 cases before the antiseptic period, 6 died; but of the 12 during that period, only 1 died, and 11 recovered. The deaths were caused, principally, by pyæmia, erysipelas, and hospital gangrene. Thence, it would appear, may be inferred “the effects of the antiseptic system of treatment upon the salubrity of a Surgical Hospital.”\*

*After-dressing.*—An incised wound should not be disturbed unnecessarily during the process of adhesion. Inflammation can scarcely be said to supervene. In the first instance, it starts this reparative process. Attended with a slight pouting and redness of the lips of the wound; this salutary degree of inflammation should not be repressed; and, being transient, inflammatory fever is not excited, from first to last, if the wound, however extensive and deep, continues to heal by adhesion. The constitution remains calm and impassive throughout the process, taking little or no notice of the local reparation effected by the part itself. Consequently, no antiphlogistic treatment, topical or general, becomes necessary; but the lightest dressings to maintain apposition, and the gentlest handling in applying them, are still sufficient.

The first dressing is not unfrequently the only one nature requires; the wound healing in two or three days, possibly in twenty-four hours. But union is not then secure, nor much before the end of a week in small wounds, and a fortnight in larger incisions. Therefore, during even the shortest period requisite for sound union, the dressings must be changed occasionally; their reapplication having reference always to some obvious and important purpose. Cleanliness, rather than readjustment of the wound, is the guiding maxim for interference. The strip of lint is to be withdrawn wet, not to disturb the lips of the wound, as yet tenderly united. The strips of plaster, also moistened to facilitate their removal, are withdrawn by both ends together gently towards the line of incision, not to undo the work of nature; and each strip is replaced by a fresh one before the next is removed, not to leave any part unsupported. The removal of sutures, if any, will be guided by the progress of adhesion, or by the accidental supervention of inflammation. Within the first twenty-four hours, *some*, at least become useless, or worse,—irritating. These sutures should be picked out, wherever, from point to point, union appears safe, or the blush of inflammation is conspicuous. Otherwise they will ulcerate their way through, and so peril the healing process. In the event of considerable swelling and tension, the lips of the wound having a

\* I have endeavoured to gather the foregoing description of this treatment, and its results, from several monographs which Mr. Lister kindly forwarded to me for this purpose.

tightly puckered appearance at the point of each suture, and a pouting or protruding condition in their intervals; *all* the sutures must be withdrawn forthwith. If thus released, the lips do not adhere, the surfaces may do so, partially or entirely.

The removal of any ligature or ligatures, is, like their application, not necessarily part of the treatment of an incised wound; and will be considered under Wounds of Arteries.

The bandage, if any, and the compresses, if any, are no longer needed when union is sufficiently firm not to risk straining the parts, by the loss of these surface-supports. Generally, the first few days will suffice. Any swelling, however, as in amputation-wounds, may yet require the partial support of a turn or two of the bandage, until tension has subsided.

Thus, one by one, the appliances of Surgery are withdrawn; one by one, these artificial props are removed; until at length, and ere long, in most cases, nature is able to consolidate the union, without further assistance.

Such then is, what I would term, the "conservative" treatment of incised wounds; an example, from first to last, utterly opposed to meddling Surgery.

### WOUNDS OF ARTERIES AND VEINS.

These Lesions are conveniently taken next in order.

WOUNDS OF ARTERIES.—*Structural conditions*.—A wound of an artery, like that of any other texture, may be incised, or lacerated; either of which lesions may be partial or complete.

*Incision, partially* extending through an artery, and practically equivalent to a punctured wound, varies in *direction*; being longitudinal, oblique, or transverse, and these are important practical distinctions (Fig. 35); so also is the variation in size of the aperture, which may be of any circumferential extent, short of *complete* division of the vessel.

FIG. 35.

*Laceration, partially* extending through an artery, is limited to one or more of its three coats; the external, and more or less of the middle coats, may be torn through, leaving only the thin inner one entire; or, the two inner coats are severed, leaving only the thick external, cellular coat untruncated. This latter condition of laceration is effected by the surgical application of a ligature. Lastly, all three coats are torn through, if the laceration be *complete*; but the external-cellular coat and cellular sheath, being tougher than the two inner coats, are drawn out from off them, which also retract; thus leaving a canal of loose cellular tissue.

The *Signs* of any such wound of an artery, are hæmorrhage, the blood having a florid red colour, and jetting out from the vessel, *per saltum*, with each beat of the heart; not escaping in a continuous stream of purple or black blood. The force, and in a degree, the rapidity of these jets are regulated by the size of the artery, or of the aperture in it, by its proximity to the heart, and by the heart's action; also by the presence or absence of certain conditions which retard or favour the free flow of blood through the vessel. Thus, pressure on the proximal portion of

artery retards, while a dependent position favours the hæmorrhage. The blood coming from the *distal* portion of vessel is dark, and runs in a trickling stream, excepting from certain arteries, as the palmar and plantar arches, which when wounded, jet arterial blood from either extremity of the vessel.

*Causes, and effects of Wounds of Arteries.*—An artery may be incised or cut with a sharp instrument, punctured with a pointed one, contused or lacerated by a blunt one, or wounded by force of a bruising or wrenching kind.

The operation of any such lesion *locally*, is to produce aneurism, if the blood be imprisoned in the textures; constituting *traumatic aneurism*,—diffused, or eventually circumscribed. Its formation will be specially described in connexion with aneurism. *Constitutionally* regarded; whether arterial hæmorrhage takes place externally, or internally, as into one of the great cavities of the body, its effects are manifested by *syncope* or fainting, more or less complete. And this may occur either by failure of the heart's action, *cardiac syncope*, and thence of the circulation; or as loss of consciousness—*cerebral syncope*; or both modes of syncope may be produced, with a fatal termination, if the hæmorrhage be sufficiently prolonged. These constitutional effects and the probability of death resulting, are proportionate to the quantity of blood lost; not necessarily by its escape *from* the body, but even when lost *to* the body as blood in circulation. Providentially, however, the imminent peril of continued hæmorrhage is lessened by cardiac syncope; suspension of the circulation, tends to arrest the escape of blood from the artery, and by thus favouring the formation of an occluding clot, it tends also to arrest the hæmorrhage.

*Reparation.*—If the vessel be healthy, the lesion is uniformly disposed to heal by coagulation of the blood and the formation of a clot or clots so placed as to arrest the hæmorrhage; a temporary provision, followed by primary adhesion, or, possibly, adhesive inflammation, whereby the vessel is permanently secured or obstructed. But this process of coagulation and adhesion is *modified* chiefly according to the structural kind of wound—incised or lacerated, either of which may also be a partial or complete division of the artery. Then, again, the direction of the wound more particularly modifies the process of healing.

1. An *incised* and *partial* division of an artery is the simplest instance. (See Fig. 35.) If the direction of the cut be *longitudinal* or oblique, it will close more readily than a transverse incision, the edges of which gape and do not fall into apposition. The elasticity of arterial tissue longitudinally makes all the difference, and in favour of *that* direction, aided also, in this case, by the circular contractility of the artery. The line of incision remains closed; blood escaping coagulates betwixt the vessel and its sheath, forming a compress, assisted by any corresponding coagulam which may have formed outside the sheath. The relative positions of the apertures in the artery and its sheath are displaced somewhat by the formation of the intervening portion of clot-compress, thus further tending to arrest hæmorrhage. The homogeneous fibrils, interspersed with many-nucleated corpuscles, of which coagulated fibrine consists, are represented in Fig. 1, p. 42. Associated with blood-corpuscles, it forms the clot. But this clot-compress is a temporary provision only. Adhesion soon follows in the line of incision, the edges being in contact. A *transverse* cut, partly through the circumference of an artery, opens, the

vessel contracting longitudinally by virtue of its elasticity. Adhesion cannot ensue. The aperture is closed by the effusion and organization of lymph *within* the artery, which thus becomes impervious and obliterated. Lost, however, for ever as a blood-conveying tube, hæmorrhage of fatal character is arrested. Nature is still victorious. The *size* of the vessel will somewhat affect the issue, which is otherwise in favour of a longitudinal incision. An artery, like the temporal, with a longitudinal slit, heals without obliteration. An artery of larger calibre, and similarly wounded, becomes impervious and obliterated. And the ultimate success of Nature's effort is apt to be marred, even when the wounded vessel remains pervious; for the internal and middle coats not adhering firmly, this defect predisposes to aneurism.

2. *Complete* division of an artery by incision is healed by a modification of the same process—clot formation, but not as a compress, being the temporary provision, lymph effusion permanently plugging up the vessel. Immediately after its division the artery retracts by its elasticity, longitudinally, into its sheath, which thus projects loosely; the mouth of the vessel contracts, even to a pin-hole opening, by its muscular contractility circularly. The retracted portion thus contracted has a conical shape, like that of a Florence oil-flask or French claret-bottle. (Fig. 36.) Contractility may be sufficient to close the vessel and prevent further hæmorrhage. In this way small arterial branches spontaneously cease to bleed in an open wound exposed to the air, or the action of cold water; but the artery having retracted, coagulation is induced within the loosely projecting filamentous sheath, which entangles the blood as it flows; and this event may be aided by cessation of the stream, owing to failure of the heart's action—cardiac syncope—another resource of Nature for the temporary arrest of hæmorrhage. Coagulation proceeds concentrically. The clot, at first pervious and transmitting a small central stream of blood, soon forms a solid mass, which, still enlarging, passes up the bore of the artery for a short distance in the shape of a small cone. This portion—internal coagulum or *bouchon*—and that in the sheath—external coagulum or *couvercle*—together form a clot, in shape like a glass stopper fitted into a decanter, to which the whole is compared by Professor Gross. The shape of Nature's product is not quite so finished off, for a small portion of the clot is insinuated between the sheath and artery beyond the point of retraction, thereby compressing the arterial aperture, while a still larger portion of an irregular shape projects beyond the aperture of the sheath. The whole clot is, however, continuous, and with these little offsets still bears the resemblance suggested. The permanent closure of the vessel is effected by the effusion of plastic lymph. Like coagulated fibrine, its organization consists, essentially, of fibrils; but those of plastic lymph result from the elongation and attenuation of cells into fibres, in various stages of development. (Fig. 1, p. 42). Corresponding in situation to the clot—*i.e.*, at the aperture, around it slightly, and extending into the vessel, the lymph in-

FIG. 36.

tervenes between it and the clot, which it gradually replaces. During this change the clot varies in appearance, being partly lymph, and partly ordinary coagulum.

The lower end of a divided artery is closed up much in the same way. According to Guthrie's observations it retracts and contracts less than the cardiac end; and the internal coagulum is altogether absent, or very imperfectly formed in many instances.

3. A *lacerated* wound of an artery, if *partial*, may extend through the external and middle coats, leaving only a thin undivided inner membrane, which still continues the channel of communication. Hæmorrhage is imminent. Or the laceration may extend through the inner and middle coats, leaving the outer cellular coat entire. Hæmorrhage threatens, or gangrene may supervene. But if the two inner coats be cut rather than torn, reparation generally takes place and secures the vessel. Such is the kind of injury purposely inflicted by the Surgical application of a ligature, which leaves the external coat undivided; and although itself noxious, as a foreign body in the very pathway of reparation, the artery becomes sealed with plastic lymph, plugged up also with coagulum, and obliterated. The details of this process, thus *artificially* induced by Surgical interference, will be described in connexion with the *treatment of hæmorrhage*.

FIG. 37.

4. *Complete laceration of an artery*—all the coats being torn through—heals without hæmorrhage or scarcely any. The process is the same as that which takes place after division of an artery by incision. But the cellular sheath and outer cellular coat are drawn off the two inner coats, which retract. Consequently the clot that forms in the projecting portion of loose sheath is larger than when the vessel is simply cut across; presenting a bulb-shaped extremity which may extend to half an inch or an inch in length. This appearance is well shown in Fig. 37, which represents a popliteal artery and vein in a remarkable case, both vessels having been ruptured by a violent twist of the knee-joint. Gangrene of the leg ensued, for which I amputated above the knee; with, however, a fatal result.

*Treatment*.—Arrest of hæmorrhage, is the first indication of treatment. *Small* arterial vessels spontaneously cease to bleed, almost immediately; the process of reparation, as appropriate to the injury, at once commencing, and even its preliminary stage proving sufficient to arrest hæmorrhage. Thus, if the vessels be divided entirely across—complete incision—as in most wounds, their cut extremities retracting and contracting soon offer adequate resistance to the escape of blood. This natural provision will be insured by exposure of the wound to cool air, or a stream of cold water squeezed from a sponge. Gentle pressure with the sponge will readily discover whether there be still any oozing from the bleeding points. *Larger-sized* arteries bleed in jetting streams of florid blood, and the resources of Surgical treatment are forthwith necessary to meet such hæmorrhage. These are successful so far as they represent, by imitation, one or other of the natural modes of arresting hæmorrhage.

1. *Compression*—*mediate*, as it is sometimes termed, when not directly applied to the bleeding vessel—may be effected either by the finger or a tourniquet, applied over the parent artery, at the most eligible spot betwixt the wound and the heart. Pressure thus applied is only a temporary resource. *Immediate* compression is effected by pressure directly applied to the bleeding vessels. A compress and bandage, applied firmly, but not with unnecessary tightness, will thus prove sufficient. This mode of compression may be regarded as representing the clot compress of nature.

2. *Ligature*.—The ligature is a Surgical appliance in imitation of a lacerated wound, partially extending through an artery—*i.e.*, through its two inner coats, which are thin and fragile, leaving the thicker and tougher outer coat and cellular sheath untern. The effectual operation of this appliance is—compression of the vessel to induce coagulation of the blood stagnant above and below the ligature, and the effusion of plastic lymph, from the divided coats, to permanently occlude the vessel in both directions; sloughing of the included ring of outer coat and cellular sheath being rendered necessary to detach the ligature. The details of this reparative process, thus induced artificially, are these.

The included portion of external cellular coat and sheath having undergone continued compression, sloughs, and is detached with the thread, in a period varying from twenty-four hours or so to about three or four weeks, chiefly according to the size of artery. Hæmorrhage would then be inevitable; but, pending the detachment of this slough-ring, effusion of plastic lymph, from the vasa vasorum, takes place, whereby the two inner coats become adherent across the area of the vessel, just above and below the ligature. At these points they curl inwards when divided, and, converging, meet together.

This condition was well seen in a femoral artery, and vein (Fig. 38), which I examined five days only after it had been ligatured when the thigh was amputated. A process of organization, therefore, above and below the ligature, accompanies the destruction and detachment of the ring of external coat embraced by the thread. Thus the artery is securely sealed. Accessory, but incidental only, to the prevention of hæmorrhage, are certain changes whereby either portion of the artery contiguous to the ligature is obliterated. The vessel having ceased to convey blood when the ligature was applied; the blood stagnant, above and below, to the nearest collateral branch, has gradually undergone coagulation in the shape of two conical clots, the bases of which accurately plug the artery on either side of the thread. The apex of the clot on the cardiac side tails off, usually opposite the first collateral branch above, through which the stream of blood, now diverted from its course, is carried off from the main. The distal clot is always less defined. At first either clot having the appearance of ordinary coagulum, subsequently it becomes mottled with paler spots, and its substance porous, and ultimately acquires a buff colour, firm consistence,

FIG. 38.

and fibrous texture. Blood-vessels, proceeding from the lymph immediately above and below the ligature, shoot into the base of either clot, and gradually extend towards its apex. Finally, these organized fibrous clots are incorporated with the lymph adjoining, which has acquired a similar structure; the coats of the unused portions of artery degenerating also assume a fibrous character, and the whole is converted into a small, firm, impervious, fibrous cord, extending usually to the first collateral branch above and below. Nature having safely severed the artery—under compression by the ligature—and securely sealed either end, has now obliterated the portions useless as a blood-conveying tube.

An artery of any notable size is most effectually and permanently secured by ligature. *Appropriate*, therefore, for the arrest of hæmorrhage which would otherwise be persistent or recurring and perilous, the ligature is applicable also whatever may be the kind of wound in the vessel, whether incised or lacerated—its extent, partial or complete—and its direction, with reference to the elasticity and contractility of the vessel. The *objections* to ligature are; the production of a slough or sloughs of arterial texture, according to the number of vessels ligatured; the introduction of a foreign body, or as many foreign bodies, into the flesh-wound—a condition proportionately antagonistic to the process of healing by primary adhesion; and, that suppuration consequently, and the sloughs, are provocative of pyæmia. The efficacy of ligature in the treatment of hæmorrhage from wounds of arteries, of flesh-wounds, and in relation to pyæmia, is to be estimated by all these considerations; and thence the value of this method of treatment as compared with that of “acupressure,” proposed to supersede it.

Certain particulars are of great moment in the *application* of a ligature; the observance of which, a due knowledge of the process thus induced for the arrest of hæmorrhage, can alone insure. It is in this light that I specially here advert to them. But they have reference also to the value of ligature, as a method of treatment; for they determine the probability of hæmorrhage recurring or supervening, and also of the healing of a flesh-wound by primary adhesion when an artery or arteries are thus secured.

The practical particulars having this twofold significance are these:—A

FIG. 39.

ligature should be applied to *cut* through the two inner coats of the artery, leaving only the outer more resisting cellular coat and sheath. Hence the ligature must be a small, round, and strong thread—fine silk twist waxed being found to answer best. Applied with sufficient tightness for this purpose, and to induce sloughing of the outer coat by *strangulating* compression. Applied *transversely* across the diameter of the vessel, and tied with a reef-knot (Fig. 39); otherwise the ligature shifting its position and loosening, hæmorrhage

recurs or supervenes when adhesion is not yet sufficiently advanced to

safely seal the vessel. Applied so as *not* to include any *extraneous* texture—a bit of muscle, a vein, or nerve; for then the twofold effect on the artery enclosed may not be produced, or sloughing may proceed more speedily in the extraneous texture than in the arterial coat, the ligature become loosened, and hæmorrhage supervene. Inclusion of a nerve-filament causes also great pain at the time, and for a considerable period in some cases. An imbedded artery may be inaccessible without including some other texture. In the most inaccessible situations—as when, by amputation, the anterior tibial artery is divided at its origin and deep in the muscles between the heads of the tibia and fibula—it is absolutely necessary to “dip” for an artery so placed. A curved needle armed with a ligature is thus carried round the vessel, and the thread tied as usual, but including as small a quantity of extraneous texture as possible. On the other hand, the ligature should *not* be applied to any *projecting* portion of the artery; the vessel being there denuded of its own nutrient vessels (*vasa vasorum*), plastic lymph is not effused, and when the slough-ring separates, hæmorrhage is inevitable. Regarded as a *foreign body*, antagonistic to healing by primary adhesion, one end of the ligature is usually cut off close to the knot on the artery, leaving only the other end to command the noose, thus reducing the quantity of foreign body in the wound by one half. The ligature or ligatures may be brought to one or other angle of the wound, and there fixed by a small piece of plaster, thus also limiting any defective adhesion to the narrow track occupied by the thread or threads. Practically, it is found they do not much interrupt the process of healing or delay the issue.

Duly observing all these suggestions of pathology, the constructive part of the process—adhesion—will generally accompany the destructive—sloughing—with even progress, and the issue of both will be contemporaneous; permanent closure of the vessel accompanying the separation of a ring of slough with the ligature. The security of the vessel is safely ascertained by gently twirling the thread between the thumb and finger. A yielding sensation shows that Nature has done her work, and that the ligature detached can be withdrawn without the risk of hæmorrhage. This, however, cannot be expected, nor should the experiment be tried before sufficient time has elapsed—the *period* varying from twenty-four hours to as many days or more, chiefly according to the *size* of the artery.

3. *Acupressure* has been proposed by Sir James Simpson as a substitute for ligature. It is essentially the “temporary metallic compression” of an artery,\* and it may be accomplished in either of three ways:—(1) By passing a long needle twice through the flaps or sides of a wound, so as to cross over and compress the mouth of the bleeding vessel or its tube; just as in fastening a flower in the lapel of our coat we cross over and compress the stalk with the pin which fixes it, and therefore pass the pin twice through the lapel. In this method a long needle is introduced from the cutaneous surface, and its extremities left out *externally*. In both the other methods a common sewing-needle, threaded with iron-wire, is used. The needle is introduced on the raw surface of the wound, and is therefore placed altogether *internally* or between the lips of the wound. The wire is only for the purpose of withdrawing the needle when no longer required. (2) In one of the methods referred to, the needle is dipped down into the

\* *Acupressure*. 1864.

textures a little to one side of the vessel, then raised up and bridged *over* the artery, and finally dipped down again into the textures on the other side. This method, therefore, is the same as the first, but that the needle is applied altogether on the raw surface of the wound and over the artery, which it compresses. (3) The third method consists in passing a needle

FIG. 40.\*

*under* the vessel, transfixing the textures once. A loop of wire is passed over the point, and fastened round the eye end by a single twist, thus compressing the artery and some surrounding tissue between the needle and the wire. This method Sir James Simpson believes to be the one which will probably be most frequently practised (Fig. 40).

In one form or other acupressure is said to be superior to ligature, both with regard to the improbability of *secondary hæmorrhage*—the probability of *healing by adhesion*, and the improbability of purulent, or other septic *infection of the blood, pyæmia*.

(1) Respecting *hæmorrhage* after amputations, in eleven cases of acupressure only one was followed by secondary hæmorrhage; whereas in eleven cases of ligature, four of secondary hæmorrhage occurred, of which two were fatal. Such were the comparative results after amputations at the Carlisle Hospital (Hamilton's Report). In other words, in that institution, secondary hæmorrhage from ligature and from acupressure was as four to one in eleven cases. Other favourable results might be added. The most recent report is that of Professor Pirrie,† who, with Dr. Keith and Dr. Fiddes, have more especially practised and advocated this mode of arresting arterial hæmorrhage. The former thus enumerates his "experience in important cases, of which records have been kept. Eleven cases of amputation of thigh, four of amputation of leg, two of amputation of arm at the upper part of the surgical neck of the humerus, one of amputation at ankle-joint, one of Chopart's amputation, two of amputation of the whole of great toe, twelve of excision of mamma, six of excision of elbow-joint, one of excision of knee-joint, one of excision of an erectile

\* Occlusion of Arteries; the femoral arteries, after Acupressure, and Ligature—in double amputation—each twenty-four hours. (Author.)

† British Medical Journal: Annual Meeting of the Association, Dublin, 1867. See also Acupressure.

tumour, one of excision of tumour on chest, one of excision of tumour on thigh (wound eight inches long), one of excision of head of fibula, three of excision of testicle, one of hæmorrhage from sloughing of hand, one of wound of hand, one of wound of upper part of forearm with great hæmorrhage, one of wound of radial artery, and one of wound of hand attended with great hæmorrhage—in all fifty-one cases, in which I have acupressed 185 vessels.”

But experience has not yet sufficiently accumulated to determine the relative value of these two kinds of treatment with reference to the improbability of hæmorrhage supervening. Nor had pathology hitherto determined this question. “We want,” acknowledged Sir James Simpson, “a series of proper experiments and observations as to the actual *pathological mechanism* by which acupressure occludes the mouths and tubes of arteries, before we can attain fixed ideas as to its progress and completion.” Accordingly, in the year 1867, I endeavoured to supply this *desideratum* by post-mortem examination of the process of occlusion in arteries, after acupressure, and its relation to the treatment of surgical hæmorrhage, compared also with ligature and torsion. The results of my observations were communicated in a Paper to the Clinical Society, in 1871. Previously, the observations of Mr. H. Lee, and Mr. J. W. West, respectively, relative to acupressure were brought before the same Society. The practical object of my inquiry was, by a due knowledge of the *process* of occlusion, to determine the proper period for the safe withdrawal of the needle from a main artery, as the femoral, and the various periods in respect to different sized arteries; rather than having recourse to the perilous mode of investigation, by tentative experience on living patients, in the treatment of hæmorrhage by acupressure. Thus would be determined the liability of secondary hæmorrhage occurring in this mode of treatment.

*Occlusion*, after acupressure, consists, essentially, in the formation of a conical clot, adjoining the transverse line of acupressure, or needle; this clot increases in length, extending up probably to the first collateral branch of artery, and it increases also in calibre, so as to completely occupy the bore of the vessel at, and for some distance adjoining the line of acupressure. Thus the artery is plugged (Fig. 41). This clot soon undergoes structural changes; becoming fibrinous in its distal portion, partly fibrinous, eventually perhaps entirely so, in its proximal portion, and there adherent to the interior of the artery. Further changes, I have not yet traced. But, it would seem highly probable that the occluded portion of

FIG. 41.\*

\* Occlusion of femoral artery after Acupressure—in amputation—five days. (Author.)

artery atrophies, and undergoing degeneration into a fibro-cellular cord, as after ligature, thus becomes permanently obliterated. In conjunction with this series of changes, as affecting the blood in the artery, and eventually the vessel itself; there are, however, no changes at the seat of acupressure—no division of the inner and middle coats of the artery, and their inversion or reduplication, and no subsequent deposition of lymph with adhesion of the divided coats of the vessel; the integrity of the artery remains unaffected by the compression of acupressure, temporarily applied, the needle serving the purpose merely of preventing the escape of blood as primary hæmorrhage, while, by arrest of the passage of blood, coagulation may be induced, and thus secondary hæmorrhage prevented when the needle is withdrawn. A firm, fibrinous, and adherent clot, was found to have formed within five days, and in a main artery—the femoral.

In *treatment*, by acupressure, therefore, the proper period for the safe withdrawal of the needle, may be inferred to be, at that period, if not earlier; without liability to the occurrence of secondary hæmorrhage.

(2) With regard to the probability of *adhesion* taking place between the *surfaces* of a wound, the arteries of which are secured by acupressure; it is alleged that the needles are, as foreign bodies, merely temporary, while their material is less irritating than that of ligatures; and that they are not intended or allowed to produce sloughing of the compressed arteries, whereby foreign bodies of worse character, in the shape of slough-rings of the cellular coats of these vessels, are produced and remain between the raw surfaces—with, moreover, suppuration. (3) Hence, also, the greater probability, apparently, of *pyæmic infection* supervening after ligature. And certainly the observations of Professor Pirrie are here to the point, not a single instance of pyæmia having occurred in his experience where acupressure has been employed by himself or his Hospital colleagues at the Aberdeen Hospital.

4. *Torsion of cut arteries*, is another method of arresting hæmorrhage, which may be regarded as an imitation of another natural process of cure. Torsion is effectual by laceration of the two inner coats of the cut end of a bleeding artery, the outer coat remaining as a loose filamentous sheath, which, entangling the blood and forming a peg, is equivalent to an accidentally *complete* laceration.

This procedure originally noticed by Galen, was revived about 1828; in France, by Amussat, Velpeau, and Thierry; and in Germany, by Fricke. In this country, recently, torsion has been practised more generally, and it seems to be attracting increasing attention. Arteries of *small* size had long since, occasionally, been commanded by a pinch and twist with the forceps; but *large* arteries, as the femoral, brachial, ulnar, and radial, have been effectually secured by torsion, in amputations of the thigh, arm, and fore-arm, as previously practised by Amussat and Velpeau.

*Occlusion* by Torsion, has been specially investigated by Mr. Cooper Forster, whose observations are published in the Trans. Clin. Society, 1870. My own observations in one case, death taking place in thirty-six hours, were communicated to the same Society, in 1871. Occlusion consists in the following changes:—At the seat of torsion, the two inner coats of the artery are torn across, and reduplicated up the vessel, perhaps in the form of a complete funicular sheath, one-fifth of an inch in length; and at the upper or smaller opening of this reduplication, or funnel, a conical blood-clot forms, occupying the bore and extending up the vessel

(Fig. 42) The twisted condition of the artery, itself usually a persistent change, and the reduplicated sheath, of the two inner coats, above, acting as a valve, are quite sufficient provision against the recurrence of hæmorrhage at the time of operation and subsequently; but there is also the supervention of clot-formation from this sheath, and extending further up the bore of the vessel.

FIG. 42.\*

FIG. 43.

Different *modes* of torsion have been recommended, and are practised. The artery may be drawn out for about half-an-inch by one pair of common serrated forceps, and its attachment seized by another pair of serrated forceps; the free portion is then twisted off by about a dozen turns of the former instrument—the method of Amussat. (Fig. 43.) Or, the end of the vessel may be simply twisted several times, without detaching it; as recommended by Velpeau and Fricke. This is the method I ordinarily practise, scarcely ever employing ligature to any artery, of whatever size; it has been much practised also by my colleague, Mr. J. D. Hill,

and it is I believe generally preferred. *Torsion-forceps* are now used; the instrument being furnished with transversely serrated points, and closed by a slide when the end of the vessel has been seized.

*Comparison of Ligature, Acupressure, and Torsion.*—The *occlusive process*, in the changes which the artery and contained blood undergo by ligature, acupressure, and torsion, may be thus summarily stated:—firstly, in all three, conical clot-formation and plugging of the vessel, adjoining the line of compression, or of twist; and, in acupressure, this is the only provision against the supervention of hæmorrhage, when the surgical appliance—the needle—is withdrawn. Secondly, in both ligature and torsion, division of the inner and middle coats of the artery, transversely, at the line of operation; followed by lymph-deposition and sealing of the vessel. This is the only additional provision against the supervention of hæmorrhage, when the ligature separates; but in torsion, the twist of the vessel is persistent, and reduplication of the divided coats, probably in a funicular form, acts also mechanically, as a valve, against the occurrence of hæmorrhage. In relation to the *treatment of hæmorrhage*—by acupressure, the formation of a clot-plug might seem an insufficient provision to prevent its recurrence, when the needle is withdrawn, that secondary hæmorrhage would then take place; yet the results of experience, already referred to (p. 262), have shown that

\* Occlusion of brachial artery after Torsion—in amputation—thirty-six hours. (Author.)

this single provision is sufficient, without the additional security of lymph-deposit and sealing of the vessel, as at the line of ligature or of twist; or the extra and mechanical security afforded by the persistency of the twist, and the funicular valve of lining membrane. But assuming the liability to the occurrence of secondary hæmorrhage to be about equal after either of the three methods of surgical treatment; the tendency to *primary union* of the flesh-wound, and the prevention of *pyæmic infection* of the system, must be very different. Torsion has decidedly the advantage over either ligature or acupressure, in regard to both these very important considerations. The twisted portion of an artery not being killed, as its subsequent adhesion shows, no sloughing of the end of the vessel ensues—when this portion is allowed to remain in the wound; yet this event necessarily and intentionally ensues after the application of ligature, or accidentally by prolonged acupressure; and no other foreign body is allowed to remain in the wound, for however short a period, to possibly provoke suppuration, as after both these methods of treatment.

**WOUNDS OF VEINS.**—The same forms of injury may occur as those to which arteries are liable, and they having been already sufficiently described, need not be repeated.

The *Signs* of any such wound are venous hæmorrhage; the blood of a purple or black colour and flowing in a continuous stream, unlike the jetting of florid red blood from an artery. The force, and in some degree the rapidity, of this stream, are regulated by the size of the vein, or of the aperture in it, by the heart's action, and its effect on the flow of venous blood; and by the presence or absence of certain conditions which favour or retard the free flow of blood through the vessel. Thus, pressure on the vein between the aperture and the heart, a dependent position of the part, and muscular action in the course of the current, favour the hæmorrhage; while, the opposite conditions retard it.

*Causes, and Effects of Wounds of Veins.*—Like an artery, a vein may be incised or cut with a sharp instrument, punctured with a pointed one, contused or lacerated by a blunt one, or injured by force of a bruising or wrenching kind. The operation of this lesion is, *locally*,—to induce diffuse inflammation of the vein,—diffuse phlebitis, if the wound be an open one, or to produce a collection of venous blood—blood-tumour, if the fluid be imprisoned in the textures. This condition will be described under Contusion. *Constitutionally*, whether venous hæmorrhage takes place externally, or internally into one of the great cavities of the body, its effects are manifested by *syncope*; either by failure of the heart's action—cardiac syncope—and thence of the circulation, or by loss of consciousness—cerebral syncope; or by both these effects, and their fatal termination if the hæmorrhage be sufficiently prolonged. These constitutional effects and the probability of death resulting, are proportionate to the quantity of blood lost, not necessarily by its escape from the body, but, even when lost to the body, as blood in circulation. Such consequences are less apt to ensue from venous than from arterial hæmorrhage; but another constitutional disturbance is *specially* liable to occur from an open wound of a vein, and more so, the larger the vessel. Air is thus apt to enter the circulation, attended with a whirling, bubbling, sucking, or lapping sound; the individual feels death-struck, he moans and breathes heavily, becomes very faint, and probably dies, in a few minutes, or at the most, in a few hours.

*Reparation.*—Wounds of Veins heal by processes apparently analogous to those whereby similar Wounds of Arteries are repaired.

*Treatment.*—The arrest of venous hæmorrhage may be accomplished, by an elevated position of the part, and the pressure of a compress secured by a few turns of a roller. Cold or astringent lotions are also of some service. Ligature should be avoided, as being apt to induce phlebitis. But this resource may be necessary in the case of a large vein, or if the vessel be so situated that pressure cannot be applied.

The treatment of diffuse inflammation of a wounded vein will be considered under the head of Phlebitis; and the remedial measures appropriate to the formation of a blood-tumour, in connexion with Contusion.

*ENTRANCE OF AIR INTO VEINS.*—The fatal result or the extremely perilous symptoms arising from the forcible introduction of air into the veins of animals, had long been known; and was at length made the subject of experimental observation by Morgagni, Valsalva, Bichat, and Nysten. But, in Surgical Practice, the accident first occurred in the experience of M. Beauchesne in 1818, during an operation for the removal of a tumour from the lower part of the neck. It was necessary to disarticulate and raise the clavicle; and while this was being done, the patient became faint, exclaimed "I am dying," and expired in less than a quarter of an hour. Dissection revealed a small wound in the internal jugular vein at its junction with the subclavian and the entrance of air through that wound caused the fatal result. The accident has since happened in the practice of Mirault, Clemot, Roux, Magendie, Castara, Dupuytren, Delpech, Bégin, B. Cooper, Erichsen, Warren, Mott, Stevens, and other Surgeons, both in Europe and America. A Commission of the French Academy was appointed to investigate the subject; and the names of Magendie, Amussat, Wattmann, and Cormack, are distinguished for the light their labours have thrown on the pathology of the entrance of air into veins.

*Symptoms.*—The *local* phenomena consist in a peculiar sound, of a hissing, gurgling, lapping, or sucking character, produced by the entrance of air, and the appearance of bubbles about the wound in the vein. The *constitutional* effects are equally remarkable; the patient is suddenly seized with great oppression in breathing, and extreme faintness, convulsive struggling, and a horrible feeling of terror and impending danger, inducing him to exclaim that he is dying. A churning noise is heard in the heart, synchronous with the ventricular systole; and the hand applied to the chest, perceives a peculiar bubbling, thrilling, rasping sensation, produced by the air and blood being whipped together within the ventricle. The heart's action becomes extremely feeble, and the pulse almost imperceptible. When only a small quantity of air has entered the circulation, the symptoms may pass off and the patient rally. A larger admission of air speedily causes death, during the convulsive struggling, or without convulsions, as if by simple syncope. The *period* at which death occurs varies, from a few moments or minutes, to several hours. When the patient survives, some hours elapse usually, before consciousness and strength are restored. In some cases, after recovery from the immediate effects of the accident, death has ensued from pneumonia.

The *mode* of death seems to be essentially asphyxia, by arrest of air-bubbles in the capillaries of the lungs, mechanically obstructing the pulmonary circulation; thence cutting off the systemic circulation, and

the supply of arterial blood to the brain, followed by syncope. Thus the heart's action continues, after respiration has ceased; and at last failing from want of its necessary stimulus, arterial blood, this organ is the *ultimum moriens*.

*Cause*.—Air enters the veins only during each act of inspiration; and in consequence of a tendency to the formation of a vacuum within the thorax, more particularly in the pericardium, during inspiration. Thence a sucking action, or “venous inspiration,” in the veins within and near the thoracic cavity; extending only to where the coats of the veins collapse. This area is limited to that part of the root of the neck and axilla where the venous flux and reflux of blood are perceptible, and the space in which it occurs has been called “the dangerous region.”

Circumstances favouring the accident:—1. The site of the wounded vein being in the dangerous region. 2. Canalization of a vein; owing to its coats being thickened by morbid deposit, or adherent to condensed, consolidated surrounding textures, or by spasmodic contraction of muscles; any of these three conditions having the effect of converting a vein into a rigid, uncollapsing tube. 3. Traction on the vein. 4. A stretched position of the part operated on. 5. The form of the wound. 6. The position of the vein in the wound; a vein cut in the corner of a wound being apt to gape, as Dupuytren's case demonstrated. 7. Deep inspiration.

*Treatment*.—*Preventive* measures consist—in making pressure on the cardiac side of the wound, during operation in dangerous localities; maintenance of a relaxed position of the part, and prevention of the stretching of veins. Any vein of considerable size, and especially in which the venous pulse is perceptible, should be avoided as much as possible. Feeble inspiration is desirable, and this is best secured by the influence of chloroform; tightly bandaging the chest to prevent deep inspiration, as some have recommended, is a perilous precaution. *Curative* treatment comprises the fulfilment of the following indications:—1. To maintain an adequate supply of blood to the brain, for the prevention of death by syncope. The patient should be placed recumbent, with the head low, and pressure should be made on the axillary and femoral arteries, so as to direct the circulation towards the brain. 2. To maintain the action of the heart by artificial respiration, and friction at the præcordial region. 3. To promote the removal of obstruction in the pulmonic capillaries, also by artificial respiration. 4. After recovery, to treat the tendency to inflammation of the lungs.

## CHAPTER XV.

### CONTUSION.—CONTUSED AND LACERATED WOUNDS.—PUNCTURED WOUNDS.

*CONTUSION*.—*Structural Condition*.—Contusion is a laceration of the *soft* textures, *subcutaneously*; the skin remaining unbroken, whereby the textures, thus injured, are protected from the air. This kind of lesion, therefore, is the connecting link between other subcutaneous lesions, by laceration, as simple fracture and dislocation; and openly lacerated, or contused wounds, compound fracture and similar dislocation; the turning

point being, exclusion from, or exposure to, the action of the air. Subcutaneous laceration of the soft textures is necessarily attended with some hæmorrhage, also subcutaneous, but which extends inwards according to the depth of the contusion. The *degree* of laceration is proportionate to the force applied externally, and to the molecular cohesion of the textures affected; the quantity of blood effused, is regulated, partly by these circumstances, but chiefly, by the vascularity of the textures; while, the effusion itself is finally determined by the resistance offered by the textures which, with the blood accumulated, together act as a compress upon the lacerated vessels.

*Signs.*—The blood, diffused into the textures interstitially, and especially into the cellular texture, is said to be *extravasated*; instead of being discharged out of the body as in ordinary hæmorrhage. Any portion of the blood which has accumulated in the cellular texture under the skin, or is thus more immediately subcutaneous, is made visible through the integument; and hence the appearance of a livid or black discoloration, the ordinary appearance of *bruise*, as seen in the first instance. If only a small quantity of blood be extravasated here, or elsewhere, the appearance is designated *ecchymosis*. Blood extravasated in considerable quantity may still present the appearance of bruise, but have also the fluid and fluctuating character of an abscess. A hard *circumscribed* boundary can also perhaps be felt. Puncture, in appropriate situations, with a grooved needle and examination of the fluid with the microscope, will determine a doubtful diagnosis. The discoloration of contusion bears a general resemblance to gangrene, but the temperature and sensibility of the part are retained, at least in a higher degree than in that condition. When extravasation of blood has taken place, deeply, and possibly into internal organs, it is declared by *functional disturbances* of a less definite character, and which of course vary with the part to which contusion thus extends.

*Causes, and Effects of Contusion.*—External force in the shape of pressure or a blow, may *directly* produce contusion; or the force may be applied *indirectly*, at some distance from the part affected. But the state of the textures may *predispose* to this kind of lesion. The elastic firmness and comparatively bloodless condition of the flesh of a prize-fighter, who has undergone "training," contrasts favourably with the flabby bloated face of one who is "out of condition," as that of the intemperate debauchee, which is ever bordering on ecchymosis.

The operation of this lesion, *locally*, is identified with its course; while its effects *constitutionally* are those which arise from other forms of Injury, and hæmorrhage; but the syncope arising from contusion is due more to the injury, itself possibly extensive and severe, than to the extravasation of blood. Therefore, the shock of injury, as manifested by the nervous system, predominates; or tetanus may supervene. [P. p. 432.]

*Course.*—The natural course of Contusion is twofold; inclining, on the one hand, to reparation subcutaneously; on the other, to sloughing, the formation of an open wound, and reparation subsequently by the process of suppurative granulation. Thus, no perceptible alteration may take place in a contused part, the bruised appearance remaining for a variable period; but absorption supervening, the originally purple or livid discoloration of a bruise fades away into a greenish or yellowish hue. Blood extravasated in considerable quantity may also remain

stationary, as a bag of fluid. But it generally undergoes changes of consistence, becoming thin and serous, and enclosed in a fibrous cyst, or thick and dark like treacle, constituting a sanguineous tumour—*hæmatoma*; or with coagulation, organization of the clot may ensue by the development of new blood-vessels. In either of these subcutaneously reparative alterations, the blood corpuscles undergo disintegration to some extent; and hence, apparently, the changes of colour, followed by absorption; and it can scarcely be doubted that the damaged structural condition of the textures is more or less reinstated. But the intimate nature of all these reparative alterations, after contusion, requires further investigation. Lastly, the most obvious change may be destruction, prevailing over any reparative effort; the blood, acting as a foreign body, induces inflammation, the products of which, commingling, form a bloody purulent fluid, extravasated amid the disintegrated textures. Gangrene is imminent, an event the more apt to ensue according to the severity and extent of contusion; gangrenous disintegration of the textures then appearing either as sloughing, or as traumatic gangrene, and converting the subcutaneous lesion into an open lacerated wound. *Hæmorrhage*, superadded to the blood originally extravasated, is another adverse issue, but less common, unless in internal organs.

Reparation by the process of suppurative granulation will be described more appropriately in tracing the course of a contused or lacerated wound.

*Treatment.*—The earliest occasion for interference is determined, not by the presence of contusion, which is naturally disposed to undergo reparation subcutaneously; but it depends on the degree of contusion and the quantity of blood extravasated. A slight ecchymosis disappears spontaneously; a more severe bruise may need help.

The *indications* are, in the first instance, to promote *absorption*, without any breach of the integument. Various topical applications have reputed efficacy. *Arnica*, I think, possesses some virtue. The tincture diluted, in the proportion of an ounce to half a pint of water, is perhaps more efficacious than spirit lotion, or any other cold evaporating fluid. Leeches are not merely useless to withdraw the blood, congealed and infiltrated; but by admitting air, and thus inducing decomposition, they are positively noxious. Moreover, they are apt to excite sloughing of the skin. Should gangrene threaten, whether from the blood acting as a foreign body, from the severity and extent of the contusion, or from both these conditions co-operating; then, indeed, *incisions*, early and free, are imperative, to give vent to blood and pus which would otherwise rapidly putrify, and to prevent sloughing, or its progress. In short, any attempt to aid restoration is now too late or inappropriate, and the rule of treatment should be to anticipate if possible, or at least accompany, the work of destruction, and forthwith remove its results. Accordingly, in the event of traumatic gangrene, amputation may become justifiable, as an extreme and rare resource.

**CONTUSED and LACERATED WOUNDS.**—*Structural Condition.*—These forms of Injury, although nominally distinct, in regard to the kind of force by which they are produced, are essentially the same. A contused or a lacerated Wound, is a sudden disintegration of the *soft* textures, with *exposure* to the action of the air. In the latter respect, wounds of this kind differ from contusion,—a subcutaneous lesion; and in virtue of the former particular, they differ from compound fracture and compound

dislocation, wherein the lesion itself is not exclusively laceration of the soft textures, these parts being involved only by the injury.

The *characters* of a lacerated wound are peculiar. It presents a torn irregular surface or cavity, with more or less surrounding swelling and discoloration, owing to effusion of blood beneath the skin, or ecchymosis. Hæmorrhage from the wound itself is inconsiderable; the vessels being lacerated. With these external appearances, the degree of pain experienced would seem to be inversely proportionate to the extent and depth of the laceration; for this kind of injury implies a corresponding destruction and death of the textures. The pain is heavy and aching. The structural alterations produced by laceration, and thence the characters of a lacerated wound, are somewhat modified by the extensibility, elasticity, contractility, and other properties of the textures. The resulting appearances are most conspicuous when a limb is drawn off, as by machinery; or abruptly struck off, as by gun-shot injury. Some textures are comparatively unyielding, and their torn extremities hang out of the stump; others break off short within the general mass. Thus, the skin being tough and elastic, it either yields higher than the included textures, or it retracts, exposing them; the muscles protrude and are everted; the tendons resisting with greater tenacity, they hang out of the stump, or giving way higher up, they are pulled out of their sheaths; nerves, for the most part break off at the surface; the vessels, especially arteries, possessing considerable elasticity, are drawn out to some length, their inner and middle coats yielding, while the external coat is prolonged over them; and their torn ends retracting, they become less pendent and exposed than any other part of the stump; lastly, the bone, having broken off abruptly, it forms the most prominent point. The stump, therefore, presents an irregular conical form, with the truncated bone as its apex.

*Causes, and Effects of Lacerated Wound.*—The force applied may be chiefly lacerating, as when an arm is drawn in between two revolving cog-wheels; or it may be chiefly contusing, as the action of a cannon-ball or other projectile. In either case the part is damaged beyond, and perhaps far beyond, the apparent extent of injury.

The *constitutional* effects of a contused or lacerated wound are those already noticed with reference to other forms of Injury, and hæmorrhage; but the syncope arising from such lesion is due more to the injury, itself possibly extensive and severe, than to the extravasation of blood. The shock of injury is always severe, sometimes overwhelming; tetanus also is apt to supervene, especially after any such wound of the hand or thumb, of the sole of the foot or of the toes. [P. p. 442.]

*Locally*—the textures, disintegrated by violence, inevitably die, to a greater or less extent. This event, which is strictly speaking *traumatic* gangrene, on however small a scale, takes place in one of two ways, or both may co-operate. Severe contusion or laceration kills the part outright; or it does so indirectly, by damaging the blood-vessels some distance off; in which case mortification is occasioned by an intervening and internal condition—deficient supply of blood to the part. In both cases, gangrene is *immediate*, or at least immediately commences; it evinces *no* tendency to *spread* beyond the seat of injury, and, in due time, is *defined* by sloughing, or by “a line of demarcation” when the injury is more extensive.

*Course.*—(1) *Gangrenous Inflammation* almost invariably supervenes,

perhaps extensively, and thus textures or a part which may not have been killed more immediately by the injury, die subsequently. Yet such gangrene also is limited to the seat of injury, and is defined by sloughing. Gangrene may, indeed, supervene on a contused or lacerated wound, without any apparent or notable inflammation, and extend far beyond the seat of injury; a whole limb speedily falling into gangrene, which spreads rapidly and is not determined by a line of demarcation. This, which has been named *spreading* traumatic gangrene, is traumatic only in that injury is the immediate or exciting cause; but its spreading and unlimited character points to some blood-condition, in operation, as the essential cause. In fact, this gangrene is the local manifestation of a constitutional condition, rather than the consequence of a local cause in operation. Its pathological significance is corroborated by two facts—that the contusion or laceration is quite subordinate in extent to the supervening gangrene; and that it occurs in those persons especially who have albuminuria, a state of urine indicative of the retention of excrementitious matters, chiefly urea, in the blood.

Either form of gangrene is always humid or moist, unlike the dry species of which senile gangrene is the representative. When a part is killed immediately, the appearances are those of the most severe contusion or bruise; when less immediately completed, as by injury to the blood-vessels, the symptoms are the same, but proportionately more gradual; and when gangrenous inflammation supervenes, the symptoms are those of inflammation rapidly passing into gangrene. But when spreading traumatic gangrene takes place, the phenomena are those of a severely poisoned wound. Gangrene is announced by great tension and livid or purplish-black discoloration, which although most conspicuous about the seat of injury, extends rapidly upwards and downwards; its progress being preceded by a slighter œdematous swelling and greenish-yellow discoloration. This, in advance, is a dying part; that, in the rear, is already dead. Emphysematous crackling, under pressure with the finger, soon leaves no doubt that death and decomposition go hand in hand. The accompanying constitutional symptoms are those of typhoid blood-poisoning; and the disease generally terminates fatally in a very few days, not later than whenever the gangrene shall have spread to the trunk.

(2) *Reparation*.—In favourable contrast with any tendency to death; the wound may evince a disposition to heal by primary adhesion, or, any irrecoverable part having sloughed and separated, the exposed surface heals by *suppurative granulation*. The process is, then, briefly this:—The local circulation is temporarily suspended. A thin coagulable lymph oozes from the surface, and forms a fibrinous film, in which white corpuscles of the blood abound. Thus the whole surface becomes glazed over, excepting perhaps any portion of fat or bone, which textures yield scarcely any, if any, such lymph. A period of *inactivity* follows, lasting from one day to ten or more, but varying with each particular texture in the wound. Some further oozing of lymph and thickening of the film may, however, continue during this period. At length, a distinct afflux of blood more than restores the circulation around the seat of injury. *Reparative* lymph begins to flow, which mingles with or displaces that which has hitherto glazed the wound. This lymph undergoes the same process of organization as in healing by adhesion—namely, self-development into fibro-cellular tissue. The deepest cells are most advanced; they are

elongated nearly into fibres. (Fig. 44.) The superficial ones remain in a rudimental state, and at length acquire the character of epithelial cells. Capillary blood-vessels spring from below, forming loops, as also seen in the figure. Each new vessel is constructed by the outgrowth of two pouches from a parent vessel. The pouches, crammed with blood-corpuscles, shoot upwards, and curving inwards, never fail to meet exactly in apposition, neither segment overshooting. They coalesce by absorp-

FIG. 44.

tion of the partition at the junction of their closed ends, thus completing a vascular loop, through which the blood, diverging from the main current and rejoining it, is continuously propelled. If, in the construction of any such vascular arch, the pouches burst, the process is then completed by the propulsion of the blood-corpuscles, the current of blood from the parent vessel being directed so skilfully as to channel a curved passage through the fibro-cellular tissue. Nerves and lymphatics do not apparently enter the substance of granulations.

The process of development having finished, healthy granulations are seen in the shape of small conical papillæ, of a glistening red colour when free from pus. The *pus cells* in suppurative granulations are either degenerate or immature granulation-cells. If the former, pus represents the *superficial* portion of organized granulation material, which, having lived its time, passes off, just as epithelial cells are detached. If immature granulation-cells, pus represents the *superfluous* portion of organizable material, which never reaches maturity. This is the more probable interpretation, considering the structural similarity or identity of pus-cells. As *immature* granulation-cells, pus ceases to be secreted when the granulations come to the level of the skin, for then, the wound or chasm being filled up, no more organizable material is needed.

Sometimes during the granulating process, granulations from opposed surfaces meet together. They may then unite—a conjunction designated “secondary” adhesion, to nominally distinguish it from adhesion primarily, as between the surfaces of an incised wound. But it takes place in the same way, by the development of fibres out of nucleated cells and the interchange of capillary blood-vessels through this medium of communication. The contractile force of granulations is supplemental to reparation in bringing down the marginal skin to their own level and diminishing the area of the wound. Thus, then, by their actual growth and possible

coalescence, aided by their contraction, granulations and skin at length become even.

*Cicatrization* commences, its purpose being to cover the granulations with skin. The marginal skin advances as a white line, preceded by a translucent bluish-white line of cuticle around the circumference of the sore. Converging, the surface gets covered; sometimes little islands of new skin form here and there, which coalesce, and shorten the process of marginal cicatrization. Newly formed and healthy *cicatrix* is thin and red, with a stretched, shining aspect, and not so supple and elastic as true skin; somewhat depressed, sometimes elevated, and always moveable. It contracts for a long while, and with considerable force, especially after burns, and acquires a pearly-white colour. It gradually becomes more supple, elastic, and moveable as part of the integument. Nature has healed, and almost effaced, the wound.

The *Prognosis* of Contused and Lacerated Wounds may be gathered, as with regard to other injuries, from a due consideration of their nature and course. It is less favourable than that of an Incised Wound; owing to the kind of structural *disorganization* in contusion or laceration. Gangrenous disintegration of the textures in a greater or less degree, is inevitable; or gangrenous inflammation, with sloughing and suppuration. The *extent* of the lesion will, therefore, much affect the issue. *Spreading gangrene* is an adventitious condition, but it is the most unfavourable consequence of contusion or laceration, as implying the co-operation of a *constitutional* cause. Healing by primary adhesion is exchanged for the slower and perhaps less effectual process of suppurative granulation; yet the latter being another mode of Reparation, must be regarded as an *eventually favourable* element in the prognosis of the lesion under consideration.

*Treatment.*—In all *superficial* wounds, contused or lacerated, and especially of vascular parts, as the scalp; the chance of primary adhesion taking place, to some extent, is not improbable, and it may be solicited with good prospect of success. Accordingly, in the first instance, the treatment is the same as for an incised wound. Foreign bodies, such as grit, portions of clothing, having been removed by a wet sponge or stream of water; replacement of the torn textures and their retention in position by the usual surgical appliances, are the immediate rules of treatment to be observed. The unknown power and resources of this or that mode of reparation, in different parts of the body and in different individuals, will ever restrain the pathological Surgeon from hastily foregoing the probability or possibility of the more advantageous mode in *any* case. But the disintegrated textures inevitably die, to a greater or less extent. Hence the kind and amount of assistance required. In the event of primary adhesion having failed entirely, and in all *deep* and *extensively* contused wounds, it becomes necessary to actually encourage and aid the process of sloughing, in order to bring into operation that of healing by granulation. The separation of sloughs is favoured by warmth and moisture, in the shape of a light poultice or spongio-piline epithem. The reparative process needs little assistance; position, rest, and protection from the action of the air by carbolic acid dressing, will suffice for the granulating of any healthy wound.

*Deep and extensively* contused or lacerated wounds of either *limb* are conditions which, in relation to profuse suppuration or gangrene, must be considered both with regard to the preservation of the limb and the life.

*Amputation.*—The propriety of amputation has regard to both these issues, which will be more advantageously considered in connexion with compound fracture and dislocation. If gangrene be allowed to *supervene*, life is endangered; if the *limb* be removed *before* the supervention of gangrene, it may have been sacrificed by such untimely interference.

The compromise of these two considerations is better determined by pathology than by empirical experience:—

(1) If the *whole substance* of a limb be involved by the injury, gangrene is inevitable; amputation, therefore, is imperative to intercept this event, and thus preserve *life*. (2) If, however, the injury be less extensive, and gangrene not inevitable; what then? Various pathologico-anatomical conditions—less than the whole substance of a limb being involved—are defined in surgical works; respecting which forms of injury, experience is said to justify amputation, in the first instance, considering the probable supervention of gangrene. But this event can never be foretold with absolute certainty in different conditions of injury; the resources of reparation and the reserve constitutional power of different individuals being *unknown*. Having regard, therefore, to the preservation of the *limb*—in cases short of its irreparable destruction—the *actual supervention* of gangrene is the only ground of assurance as to the urgent necessity for amputation.

This compromise between limb and life may be thus stated:—whenver a limb is destroyed, by injury, and life would be perilled by gangrene supervening, (primary) amputation is imperative; whenever a limb is not entirely destroyed, the *rule* should be, to give the limb *its* chance of recovery, by waiting for gangrene; but in that event (secondary) amputation becomes necessary, and further delay would peril life, without the compensating probability or possibility of preserving the limb. Duly weighing both these conditions; the Surgeon will ever be prepared to estimate the urgency of amputation in any particular form of contused or lacerated wound—and otherwise than when destructive of the whole substance of a limb.

The subordinate conditions of injury, necessitating amputation, are thus enumerated in Mr. Erichsen's work on Surgery. It should be observed that some of them are, not conditions of contused or lacerated wound alone, but as associated with Fracture, compound.

(1) If the soft parts be extensively stripped away from the bones, though these be entire, so much sloughing and suppuration would ensue as to leave a useless limb, and amputation should be performed.

(2) If a large artery, as the femoral, is lacerated at the same time that the soft parts are extensively injured, and the bone fractured, amputation is required in order to prevent the occurrence of gangrene.

(3) If the knee be largely opened, with laceration of the soft parts, and perhaps fracture of the contiguous bones, the limb must be amputated. Corresponding injuries of the ankle, shoulder, and elbow joints, may admit of resection rather than of amputation.

(4) Bad crushes of the foot have a great tendency to run into gangrene, and hence require amputation. In the hand, on the contrary, very extensive injuries are often recovered from, without this operation being necessary; and in many cases partial resection may be substituted for it.

The *time* also, as well as the conditions, for the performance of amputation is equally represented by the foregoing rules. Amputation for injury, in general, is commonly divided into Primary and Secondary;

the *primary* being that which is performed during the first twenty-four or thirty hours, before any inflammation has commenced; the *secondary* being amputation performed after that period, or at least before the supervention of inflammation and suppuration. Amputations performed in the intervening period, between twenty-four hours and inflammation, are sometimes designated *intermediate*. With regard to contused and lacerated wounds; the proper *time* for amputation under different circumstances, is expressed by these terms—primary and secondary, as having reference to the performance of the operation before or after the occurrence of gangrene; in accordance with the rules already laid down.

*Part for Amputation.*—In the event of *gangrene*, the *seat* of amputation or the portion of limb to be removed, should not be determined by waiting for the formation of the line of demarcation between the living and dead parts. Amputation must be performed at once, and sufficiently high above the seat of injury to prevent the recurrence of gangrene in the stump. The foregoing considerations relate exclusively to purely traumatic gangrene. *Spreading* traumatic gangrene being the local manifestation of some morbid condition of the blood, its supervention is so far less likely to be intercepted by the primary amputation of the injured part. On the other hand, gangrene appearing in the stump, would frustrate the intention of the operation with regard to the preservation of life. When spreading gangrene has supervened, the Surgeon is placed in this dilemma in regard to the part for amputation:—if the operation be performed without waiting for the line of demarcation, gangrene will probably reappear in the stump and death ensue; if the operation be postponed, for this purpose, the gangrene spreads rapidly up to the trunk, and then death is inevitable. Considering that the injury is the exciting cause of this gangrene, amputation had better be performed at once, and at some height above the apparent seat of injury. But, in selecting a sound part of the limb, and not merely that which may recover itself as a stump; it must ever be remembered, that while the damage done by contusion or laceration is more extensive than may appear on the surface, the destruction wrought by spreading gangrene, especially in the cellular texture, has even a wider range up the limb, than as declared by any discoloration of the skin. The safest parts for amputation are, probably, at the shoulder joint, when the arm is involved; and in the upper third of the thigh, when the leg is affected as far as the knee.

The *after* or *constitutional* treatment is fully considered in connexion with the *general* pathology of Gangrene.

**PUNCTURED WOUNDS.**—*Structural condition.*—A Punctured Wound is a more or less contused and lacerated wound; varying in *depth*, but of greater extent in this direction than superficially. Structures may thus be injured far beyond what appears to be the extent of injury, by the aperture in the integuments. Other kinds of Wound—the incised and the purely contused or lacerated—may indeed be *complicated* by their depth; a punctured wound is characterized by this additional element. Thence, penetration of an artery and the formation of traumatic aneurism, may complicate a punctured wound in any part. Penetration of the brain complicates a punctured wound of the skull; and similar injury of the lung or heart, or of one or more of the abdominal viscera, may complicate a punctured wound of the thoracic or abdominal cavities, respectively.

The *external characters* of a punctured wound are comparatively unim-

portant, and not characteristic. Varying in size, from a pin's point to a bayonet-thrust or an aperture of larger size; its shape differs with the form of the penetrating instrument; the margin of the aperture is irregular and the surrounding integument bruised, if the wound was produced by the penetration of a blunt-pointed instrument; and this laceration and contusion are the more conspicuous if the weapon was of increasing size from the point upwards, as a bayonet. The hæmorrhage cannot be estimated by the quantity of blood which escapes externally. The narrow track of a punctured wound and laceration of the textures, rather impede the escape of blood, and are favourable to the formation of traumatic aneurism. If the wound extend into an internal cavity, as the thorax, hæmorrhage may take place yet more abundantly without a corresponding escape of blood from the aperture externally.

The Symptoms connected with the penetration of *particular parts*, perchance the viscera, are specially significant, in virtue of the function of the part which is thus involved; but, as not pertaining to the general pathology of Punctured Wound, such symptoms are here omitted. Each successive injury, in depth, is less open to detection, owing to the narrow track of the wound. The *diagnosis*, therefore, must be determined by *functional* symptoms; and it will be remembered that structures of vital importance, possibly, may be implicated, beyond the otherwise apparently simple puncture, viewed externally.

*Causes, and Effects of Punctured Wound.*—Any pointed instrument, sharp or blunt-pointed—*e.g.*, a pin, an old rusty nail, a pen-knife, or a bayonet—represents the whole class of causative agents. Contusion and laceration are proportionate to the bluntness of the penetrating instrument. The *constitutional* effect of a punctured wound, consists partly, of syncope due to hæmorrhage; partly and perhaps principally, of shock to the nervous system; and here again, both are generally disproportionate to the apparent importance of the local lesion, which, by its depth may involve large blood-vessels and nerves, and possibly implicate a vital organ. Tetanus is another constitutional condition not unlikely to occur.

*Course.*—Sloughing ensues, more or less in extent, along the track of the wound, accompanied with suppurative discharge; but, eventually, it heals by granulation. If the textures are not much contused nor lacerated, the wound may heal by primary adhesion; and this, although the depth of penetration may have been considerable, extending even into a great cavity and involving an important organ. Thus, in one case, under my observation, after a stab in the back with a fork, which entered the lung; union of the flesh-wound speedily ensued, and the lung-symptoms also subsided. In another case, after a similar stab in the loins, penetrating the kidney; this mode of healing occurred, and the hæmaturia disappeared. Other remarkable cases are on record [P. pp. 154 and 766]. Apart from this general vital history, a punctured wound extending into any internal organ, exhibits a series of phenomena peculiar to the particular organ implicated; and thence the completion of the vital history of this form of injury, as occurring in different parts of the body, belongs to Special Pathology.

*Prognosis.*—The prognosis of Punctured Wound is partly analogous to that of any other contused or lacerated wound. It is unfavourable in so far as the kind of structural *disorganization* is that of contusion or laceration. Sloughing and suppuration to some extent are almost inevitable. The presence of any *foreign body* in the wound has a

similar influence. But the prognosis is specially unfavourable according to the *depth* of the wound, or the number and functional importance of the parts implicated, as complications of the wound. Injury to large blood-vessels, nerves, or an internal organ, are thus, severally, unfavourable conditions; and proportionately to the importance of the functional disturbances thence arising.

The subsequent course of a punctured wound, in its undergoing reparation by suppurative granulation, is an *eventually favourable* ground of prognosis.

*Treatment.*—The first indication is to arrest hæmorrhage, which obviously claims immediate attention when it occurs in any considerable quantity. Pressure, by means of a compress, will generally prove sufficient, unless a large artery be punctured, when it will be necessary to ligature the vessel above and below the aperture, by cutting down in the track of the wound, if it can possibly be thus secured. The removal of any foreign body is another obvious indication, whenever it can be safely fulfilled. A portion of clothing may have been thrust so deeply into the wound, and possibly into some internal organ, that its presence cannot be ascertained with certainty, nor its removal effected with safety, and without unwarrantable mutilation.

Guided by the processes of reparation, healing by primary adhesion should be *attempted* in all cases; but the prospect of success will depend on the comparatively simple character of the wound, by the less circumferential contusion, the absence or removal of any foreign body, and the arrest of hæmorrhage. Failing in most cases to induce adhesion, the process of suppurative granulation is the alternative to be solicited, as in the usual treatment of a contused or lacerated wound.

## CHAPTER XVI.

### GUNSHOT WOUNDS.

**GUNSHOT WOUNDS.**—*Structural Condition.*—Of Complicated Injuries, none are more interesting and important than Gunshot Wounds. But they chiefly concern the Military Surgeon, although the general Surgeon may occasionally be called upon to undertake the charge of such injuries in civil practice. It will, therefore, be doubly necessary to fully consider the guiding elements of their pathology and treatment.

Gunshot wound is, essentially, a contused and lacerated wound; but varying in *extent* and *depth*. The latter element is always a critical consideration. Structures may thus be injured far beyond what appears to be the extent of injury, in connexion with the aperture or apertures in the integuments. If any part, as a limb, be shot away entirely, as by a cannon-ball, the extent of injury is more openly declared. Other kinds of wound—the incised, and the purely contused or lacerated—may, indeed, be thus *complicated*; a gunshot wound is characterized by either additional element. Thus, penetration of an artery, with the formation of traumatic aneurism, may complicate a gunshot wound in any part. Penetration of the brain complicates a gunshot wound of the skull; and similar injury of the lung or heart, or of one or more of the abdominal viscera, complicates a gunshot wound of the thoracic or

abdominal cavities respectively. Compound Fracture or Compound Dislocation not unfrequently complicate the more severe forms of Gunshot injury.

The *course* of a ball in the body is determined by its shape and velocity. The round musket-ball—formerly in use exclusively, and propelled with a velocity which scarcely reached eighty yards, revolving, also, on its axis at right angles to its transit—was turned aside by the slightest obstacle. On striking the body, the resistance offered by clothing, or, on penetrating the skin, by a bone, and, indeed, the different resisting media of different structures, would deflect the ball from its course, and make it assume a circuitous and perchance most extraordinary route; ultimately lodging in the body in many cases. Various remarkable examples are recorded by authors on gunshot wounds.\* Nowadays, the cylindro-conoidal rifle-bullet, generally used, and propelled with a velocity true at 1000 yards or more, pursues its course straight through the body, and out again, in most cases. An apparent deviation is sometimes due to the Surgeon omitting to view the patient in the position he was when the ball entered; and, occasionally, though rarely, a real deviation, possibly a circuitous course, is caused by an accidental concurrence of circumstances, especially when the velocity of a conoidal bullet has become diminished.

Of the various *textures*, none suffer so much damage as bone by the penetration of a conoidal bullet. Piercing and passing through the soft parts, it splits and comminutes any bone in its way, producing fissures which extend into neighbouring joints; the greater destructiveness of this shaped projectile, resulting from its wedge-like action, and the peculiar resistance offered by the osseous texture. The bullet itself becomes somewhat changed in shape; its apex being flattened and reverted, if it strikes point-blank; or planed from its apex towards its base when it strikes parallel to its line of flight.

*Foreign bodies*, of various kinds, are often lodged in a gunshot wound, and not unfrequently lie deeply buried; thus constituting another complication.

The *lodgment* of any foreign body is determined by its shape and velocity, chiefly by the latter circumstance. A conoidal ball, with a considerably reduced speed before entering the body, will lodge, more or less deeply; while a round ball, although at full speed, having taken a circuitous route in the body, may become expended, and thus effect a lodgment. Bullets scattered from canister or spherical case, are liable to lodge; owing, apparently, to disturbance of their course in the primary discharge, and secondarily, by explosion of their containing case. (Longmore.) Grape-shot lodge occasionally, and possibly after a very devious course, in the body. More rarely, a cannon-ball lodges, and remains concealed. A ball weighing 8 lbs. was buried in the thigh, and discovered only by amputation. (Guthrie.) In another case, a ball weighing 5 lbs. was found also in the thigh by amputation. (Larrey.) Penetrating fragments of shell, if projected edgeways, almost invariably lodge, and are frequently concealed; of which some remarkable instances are mentioned by Mr. Longmore.†

In exceptional cases, a *small scale* may be detached from a leaden bullet, and this lodges in the wound. Such portions may occur,

\* System of Surgery, 1861, ed. by T. Holmes, art. by T. Longmore.

† Op. cit. p. 15.

irrespective of the shape of the bullet, from a cylindro-conical as well as from a round bullet; and instances of either kind came within the experience of the last-named authority during the Crimean war.

Other *kinds* of foreign bodies, and of various shape, as gravel, bits of wood, portions of clothing, &c., are not unfrequently found, or remain deep in a gunshot wound; any such substance being additional to the projectile, or the only extraneous substance.

A portion of the body of another individual close at hand, may be struck off by gunshot injury and driven into the one who is the subject of examination. Any such fragment is thus introduced by *indirect* participation in the gunshot injury. A double tooth, belonging to a comrade was found embedded in the eyeball, in one case; a portion of the jaw of a companion was driven into the palate in another case; while, in a third case a piece of the skull was found impacted between the eyelids, the fragment having been shot off the skull of a soldier close by. And, generally speaking, the fragment thus introduced comes from a corresponding region of the body struck by the shot. (Longmore.)

*Signs.*—The external appearances produced by gunshot wound, will depend on the size of the projectile and its velocity.

*Number of Apertures.*—A small penetrating body, as a bullet, produces;—(a) An aperture of *entrance*, and, if the ball lodges, this is the only aperture. But, the ball may have passed round and out at this aperture; or, it may have rebounded owing to the elasticity of the part struck, as the cartilages of the ribs;\* or, having lodged temporarily, it may have been withdrawn in a pouch of clothing.† There being only *one* aperture is, therefore, no *sure* sign that the ball has *lodged*. (b) *Two* openings—one of *entrance*, another of *exit*—are produced if the ball penetrates with sufficient velocity to pass through the limb or body. (c) More than one, perhaps *several* openings of *entrance* are produced occasionally. Thus, a bullet having first struck any hard resisting object, and split into pieces, two or more portions may recoil and wound a bystander; producing as many entrance-apertures. In one such instance, a ball split into five pieces by first striking against a rock; and all five portions entered the body of a soldier a few paces off. But, the number of openings are not necessarily the same as that of the balls which *penetrate*. For example, of three balls, two may have the same aperture of entrance, and of exit also. This coincidence happened in the case of a youth who was shot through the abdomen; “that *three* balls went through him was evident, for they afterwards made three holes in the wainscot behind, but two very near each other.” (Hunter.) (d) More than one, perhaps *several* openings of *exit* are formed in some cases. Thus, a bullet having struck a ridge of bone and *split* into pieces, two or more portions may pass through; producing as many exit-apertures. In one instance, a ball having split into two pieces by striking against the sharp crest of the right tibia; both portions passed through the calf of that limb, forming two openings of exit, and then severally entering the other calf, produced five openings altogether.‡ A portion or portions of a *split* ball may *lodge*. Instances of this kind are recorded, where the ball had struck the edge of the patella, or the spine of the scapula.§ In like manner, when several *balls*, say three, have entered; one or more may *lodge*. There being an aperture of *exit* is, therefore, no *sure* indica-

\* Guthrie, ed. ii. p. 19.

† Dupuytren, *ibid.* p. 428.

‡ Clin.-Chir. Dupuytren, t. ii. p. 426.

§ Obs. in Milit. Hosp. in Belgium, J. Thomson.

tion that one or more balls, or a portion of one, has *not* lodged; unless, in the latter case, the entire ball can be found. And, moreover, the *number* of exit-apertures are not necessarily the same as that of the balls which entered, or of the portions into which any one ball may have split. (e) *Several* openings, both of *entrance* and of *exit*, may be produced, and by a *single* ball. In one case, a ball passed through the hand, then the skin of the groin, and next the left buttock; thus causing six openings.\* In another case, six openings also were caused by a single ball having passed through both thighs and the scrotum. (Guthrie.)

*Appearances of the Entrance and Exit Apertures respectively.*—They are tolerably distinctive. (Fig. 45.) The aperture of *entrance* is a small, nearly circular opening, its margin inverted, slightly torn, and surrounded with an areola of purple ecchymosis. The aperture of *exit*, is larger and more irregular, its margin everted and more lacerated, showing the subcutaneous fat, and with less surrounding ecchymosis. These differential characters depend chiefly on the diminished velocity of the ball after its passage through the substance of a limb or the body. Consequently, the appearances of the entrance-opening vary somewhat in different cases, chiefly according to the speed of the ball; and its characters may re-

FIG. 45.

semble those of the exit-aperture. A larger penetrating body than a bullet, and one of an irregular form, as a small piece of shell, produces an opening similar to that of a bullet; but it is more lacerated and less circular, of small size also as compared with the fragment, this peculiarity resulting from the slanting direction in which it penetrates. Generally there is no exit-aperture; such a projectile lodges, owing to its comparatively less momentum. A still larger penetrating body and of an irregular shape, as a larger fragment of shell, produces an aperture yet more lacerated, and of even smaller size as compared with the fragment. It also not unfrequently lodges.

A large-sized projectile, as a *cannon-ball*, may penetrate and pass through the body, producing an entrance- and an exit-aperture, which

\* Hist. Chir. du Siège d'Anvers, Hippolyte Larrey, 1833.

respectively resemble those caused by a smaller projectile, as a bullet ; only that the characters of either aperture are presented on a much larger scale. If, however, such a projectile as a cannon-ball strikes one of the extremities, it carries away the entire limb, as if transversely amputated ; leaving a contused stump, purple and pulplified. The stump is less abruptly truncated and more lacerated, if the ball impinge with diminished velocity, as when bounding along the ground it strikes off a limb. In both these forms of cannon-shot injury, the ball impinges in a direct line. If a cannon-ball strikes the body in a *slanting* direction, thus brushing the surface, and especially if when moving with a greatly diminished velocity, it rolls over the part ; in either case, the skin may not be broken, its elasticity apparently preserving that texture entire, and scarcely any discoloration marks the course of the ball. But the gravest subcutaneous disorganization of other textures is produced ; even to the pounding of muscles, vessels, nerves, and bone, or of the viscera. Such internal lesions, unaccompanied by any corresponding external signs, were formerly known as “wind-contusions,” and attributed by French authors, to the “vent de boulet.”

*Hæmorrhage* of an arterial character, may attend a gunshot wound ; and sometimes proves fatal almost instantaneously. A gush of arterial blood is seen, and then and there a pallid corpse. Generally, however, the accompanying laceration secures the vessel, as already described (Chapter XIV.), and prevents the escape of any considerable quantity of blood, at the time of injury. Puncture by a spiculum of bone, occasionally, will cause primary hæmorrhage ; but a bullet may pass between an artery and vein in contact, as the femoral vessels, without opening either vessel ; their elasticity apparently preserving them intact.

The *pain* of a gunshot wound is worthy of notice as a symptom. In the first instance, it is either like the sharp stroke of a cane, or a dull heavy blow ; differences due, perhaps, to the degree of contusion. The pain may be referred to a part remote, more or less, from the seat of injury. This want of localization, coupled with the inconstant and indefinite character of the pain itself, evinces its inferior *diagnostic* value as a symptom, compared with the signs already described. For a short time after the injury, the sensibility of the part is numbed ; pain succeeding, and with increasing intensity as inflammation and tension supervene.

The symptoms connected with the penetration of *particular parts*—perchance the viscera—are specially significant, in virtue of the function of the part, which is thus injured ; but, not pertaining to the general pathology of gunshot wounds, they are here omitted.

*Causes ; or kinds of Projectiles in Gunshot Wounds, and the Effects of these Injuries.*—The *shape* of projectiles used in warfare presents several varieties, the chief of which are—spherical, as cannon-balls, grape, musket-shot, and shell ; cylindro-conoidal, as balls belonging to rifled cannon and rifled muskets ; irregular, but generally bounded by linear and jagged edges, as fragments of shells and splinters. (Longmore.) In point of *size*, projectiles vary from a rifle bullet to the largest sized cannon-ball or shell. The material and *density* of projectiles are less various ; being either lead, as the common bullet, glass, as some hand-grenades, or cast iron, as cannon-ball or shell and all other missiles.

The *momentum* of a projectile is represented by its weight and velocity. The *velocity* of different kinds of projectiles varies considerably. Accord-

ing to a table published in 1851, the common musket-bullet moves at the rate of 850 miles per hour, the rifle-ball, of that date, at 1000, and the 24lb. cannon ball at 1600 miles per hour. But the musket-ball then could not be depended on to hit an object beyond 80 yards, and the rifle not further than 200 to 250 yards; while the present Enfield rifle is sighted to 900 yards, and the short Enfield to 1100 yards. (Longmore.)

The *kind of motion* imparted to different projectiles and thence their course through the air, is a difficult question, which can only be analysed and determined mathematically, and is in fact a very important branch of dynamics. Different kinds of motion have to be considered in combination, and as resulting from the propulsive force, subject to the law of gravity. A ball discharged from the old smooth-bore musket, has a double motion; it revolves on its axis at a right angle to the line of flight. A ball discharged from a rifle-bored musket or rifle, has also a double motion, but of a different kind; it revolves on its axis in the line of flight. The *angle* at which a projectile strikes may be said to be accidental in many or most cases, and unconnected with the missile itself or its motion. Striking frequently at or nearly a right-angle; one kind of missile—the shell—exploding on the ground, scatters its fragments upwards, and thus any such fragment will strike probably at an acute or obtuse angle.

The *penetrating* power of a projectile is determined mainly by its shape and velocity. The cylindro-conoidal form is very penetrating, in virtue of its mechanical advantage as a wedge. Thus, supposing one of the old musket bullets to strike a limb—at eighty yards, and an Enfield rifle conical bullet of the same weight at eight hundred yards; the rate of velocity being equal in either case, the injury from the latter *shaped* ball may be expected to be much greater than that from the former. (Longmore.) The influence of *velocity* is well known, and shown by the different effects of the same kind of missile according to its speed. A spent cannon-ball, rolling or bounding along the ground—ricochetting, may carry away a limb; whereas the same ball at full speed would level a line of men. But the former injury, occurring possibly when the cannon-ball is rolling along so slowly, as apparently to have no more force than a cricket-ball, shows also the influence of *weight* as an element of the momentum. *Density* is an important consideration respecting the power of penetration. For example, in the two most perfect of modern English rifles, the Enfield and the Whitworth—the projectiles and charges being of the same weight—when lead is used, the penetration at eight hundred yards is one-third greater from the Whitworth than the Enfield; but, if a less yielding material be used, as when lead is mixed with tin, its penetration is as 17 to 4, at eight hundred yards. (Longmore.) The *kind of motion* has certainly some relation to the penetrating power of any projectile. If spinning, like a top, at a right angle to the line of flight, as a bullet discharged from the old smooth-bored musket; the projectile is easily turned aside from its course; whereas, the screw-motion of a ball, discharged from a rifle-bored tube, coinciding with the line of flight, is very penetrating. Lastly, the *angle* at which a projectile strikes, must affect its penetration. A right angle will be more effectual than an acute or obtuse angle; the impinging body having a tendency to glance off in striking at the latter angle. Other bodies are sometimes associated with projectiles as *indirectly* causing wounds, additional, perhaps, to gunshot

injury. Such missiles may be stones, splinters of wood or bits of iron from gun-carriages, portions of clothing or coins, and fragments of bone from a wounded comrade. Having borrowed their motion from the projectile itself, of whatever kind—perhaps a ball already spent—any such body strikes with a proportionately diminished impetus, and with different degrees of effect under various circumstances affecting its own displacement, shape, and so forth.

The *effects* of a gunshot wound *locally*, and *constitutionally* are quite *analogous* to those of a punctured wound, or of any contused and lacerated wound. Parts are damaged far beyond the apparent extent of injury. Thus, the textures are killed to a greater or less extent along the track of the wound, and a corresponding tubular slough is eventually formed. Shock, rather than syncope from sudden hæmorrhage, is the primary constitutional disturbance. This sloughing is more extensive and the shock more overwhelming and prolonged, when caused by projectiles of modern design; their more deadly character being due to their greater power of penetration.

Considerable importance has been attached to shock, in the sense of *concussion* of the whole body, by a heavy projectile, as a cannon-ball. But this can only occur when the velocity of any such projectile is so much reduced as to give time, in striking, to overcome the inertia of rest in the body. A cannon-ball at full speed may carry away a limb without knocking down the individual, who falls simply by the sudden shock of injury to the nervous system. Tetanus is of common occurrence. But its frequency has varied much in different campaigns, and under different climatic influences. In the Peninsular War, it was estimated to occur in about 1 case in every 200 wounded; in the Schleswig-Holstein War, 1 in about 350 cases. In the Crimea, tetanus appears to have been of rare occurrence. Alcock's estimate of 1 to every 79 wounded is too high. After naval engagements, the mortality has often been high. Sir G. Blane states that, after Rodney's action, out of 810 wounded 20 were attacked with tetanus, being 1 in 40. But sudden change from heat to cold is the most frequent cause of tetanus among the wounded. This was observed after the battles of Moskowa, Bautzen, Dresden, Chilianwallah, and Ferozepore. The above statistics include the proportion of cases of tetanus arising from all kinds of wounds, besides gunshot.

*Consequences.*—The vital career of a gunshot wound, is analogous to a punctured wound, or of any contused and lacerated wound. *Gangrenous inflammation* invariably supervenes, perhaps extensively, along the track of the wound; and thus textures which may not have been killed more immediately, die subsequently. The *total* result is represented by the slough which forms. About the fifth day of a gunshot wound, this slough begins to loosen from the margin of either aperture, if two exist, and the line of demarcation between the living and dead tissues is clearly visible; about the tenth day, the slough or sloughs may be seen hanging out of the openings, and come away in the dressings. A tubular casting of slough had hitherto intervened between the living tissues surrounding the course of the wound and prevented its union by adhesion. Suppurative granulations supervene, and the wound heals, or should heal, from within outwards.

Pending this process of reparation, tension is often extreme and extensive, and suppuration equally profuse and diffused. *Secondary*

hæmorrhage is not an uncommon event. It occurs most frequently on the sixth day. (Baudens.) Arteries which did not bleed primarily, or which were only slightly grazed, may now burst forth. Such hæmorrhage, if not suddenly fatal, may be uncontrollable, from its depth or in a disorganized part, or ultimately fatal in an individual already reduced by suppurative discharge.

An *unextracted ball* plays a singular part in the subsequent history of a gunshot wound. Constant suppuration, and exfoliation if the ball be lodged in bone, are events which might be expected. But the ball may move from its first lodgment, and travel to some distance, in a devious course, and ultimately find an exit or still remain in the body. Various functional disturbances arise during these peregrinations. Again, the ball may become encysted in dense fibro-cellular tissue, and then being stationary and isolated in a sac, it occasions little or no inconvenience. Or, a long canal-like cyst may form, in which the ball, although imprisoned, moves freely up and down. Apart from this general vital history, a gunshot wound extending into any internal organ, exhibits a series of phenomena peculiar to the particular organ implicated; and thence the completion of the vital history of this form of injury, as occurring in different parts of the body, belongs to Special Pathology.

*Prognosis.*—The prognosis of Gunshot Wound is partly analogous to that of any other contused or lacerated wound. The kind of structural *disorganization* is important; as leading inevitably to sloughing and supuration. The presence of any *foreign body* in the wound has a similar influence. But the *extent* and the *depth* of a gunshot wound, will much affect the issue. The prognosis is specially unfavourable according to the number and functional importance of the parts injured, as complications of the wound. Injury to large blood-vessels, nerves, or an internal organ, are thus, severally, unfavourable conditions; and proportionately to the functional disturbances thence arising. Compound Fracture, and Compound Dislocation, are obviously most serious complications of gunshot injury.

The subsequent course of the wound in its undergoing reparation by suppurative granulations, is an *eventually favourable* ground of prognosis.

*Treatment.*—*Immediately* after a gunshot wound, certain requirements demand instant attention, as to hæmorrhage, position, and shock.

1. Arterial hæmorrhage, whether in the form of a jetting stream or a rapid dripping of blood, must be arrested forthwith. Abundant venous hæmorrhage is scarcely less perilous. If a limb be the seat of injury, a tourniquet should be applied, so as to command the main vessels. The same rule holds good when the limb is struck off, as by a cannon-ball; a tourniquet should be applied above the stump. In the absence of this instrument, a substitute may be readily made, by means of a stone about the size of an egg, rolled in the middle of a pocket-handkerchief and placed over the main artery; the ends of the handkerchief being drawn around the limb and secured in a knot, and then twisted up tightly with a piece of stick or the hilt of a sword passed under it. A compress and an elevated position of the limb, are more suitable when the hæmorrhage is purely venous. The part may be covered with cold wet lint, as a soothing application. If the head or neck be wounded, hæmorrhage, whether arterial or venous, must be arrested by pressure; and cold applied.

2. Attention to *position* is important. A limb should be laid in an

easy position; and fixed during the removal of the wounded person to Hospital, in order to prevent any disturbance of the injured part from shaking or from spasmodic action of the muscles. This precaution will be the more necessary when compound fracture or dislocation complicates the injury. If the chest be shot through; the patient should be laid on the injured side, and cold applied. If emphysema occur, or if air escape freely through the wound, a broad rib-roller should be applied. If the abdomen be wounded, the patient should be laid on the injured side; or, if the wound be central, on his back, with the knees drawn up over a pillow or knapsack. Any portion of protruding intestine or other viscera, must be gently cleansed with water and at once returned.

3. *Shock*, or sometimes *hæmorrhagic collapse*, may be most perilous; and brandy, wine, or other stimulant, must be administered to preserve life. Cold water may be given freely to allay the parching thirst which speedily ensues from loss of blood.

The *subsequent* indications of treatment comprise—the permanent arrest of hæmorrhage.—Extraction of foreign bodies.—The management of inflammation, and sloughing; and—the conditions requiring amputation.

4. *Hæmorrhage*.—The permanent arrest of hæmorrhage may first demand attention. If arterial, the application of a double ligature to the wounded vessel may be necessary; the wound being sufficiently enlarged perhaps by an incision for this purpose. But it is seldom requisite to have recourse to ligature for primary hæmorrhage after gunshot injury. When a limb is torn off, leaving a stump, the lacerated vessels soon cease to bleed. Venous hæmorrhage must still be arrested by pressure, and elevation of the limb.

Other indications for interference with the wound are best determined by examining the patient in the position, as nearly as it can be ascertained, in which he was relatively to the projectile that struck him. In any other posture, the apparent course of the ball in the body, and thence also the probable extent of injury or the parts implicated, would be modified by muscular action and by the various degrees of elastic retraction of the wounded textures.

5. *Foreign bodies*.—To detect any such substance, the finger is the best searcher or probe. In case of doubt or difficulty of examination as to the lodgment of a *lead*en bullet, Nélaton's probe offers the requisite facility and certainty of diagnosis. In the well-known instance of Garibaldi, it will be remembered that a ball was detected with this instrument by Nélaton, after search had been otherwise made, repeatedly in vain.

*Enlargement of the Entrance Aperture*.—A slight incision is sometimes absolutely necessary for the removal of a *bullet* or other foreign body; but the rule of practice which formerly prevailed of invariably enlarging the aperture by incision and to some considerable extent was an error; suggested by the false pathology of thus converting a supposed "poisoned" wound into a simple incised wound, and of giving free vent to the noxious discharge. Any foreign body, of *irregular* shape,—*e.g.*, a fragment of shell, more generally needs release to effect its dislodgment and extraction; the circumstances in this case at once showing the necessity, and regulating the extent, of incision. But unless for an obvious purpose, the *rule* should be to avoid making any enlargement of a gunshot wound, any extension of the original injury.

To remove a bullet some form of bullet-extractor is generally requisite or advantageous. The most convenient form is here represented. (Fig. 46.) Any kind of forceps is somewhat objectionable, owing to the dilatation of the textures in using the instrument. A bullet lodged in bone is, perhaps, most readily extracted by an elevator, aided by gouging away any overhanging portion of bone. Any other foreign body, as a portion of clothing, which might be mistaken for some natural texture, should be searched for with the finger and removed by manipulation rather than with forceps, which are apt to seize both indiscriminately. Examination of the dress will probably show whether a portion was carried with the shot into the wound. It should, however, be remembered that any such fragment may have been withdrawn in undressing the patient. Foreign bodies are *eligible* for removal, according to the patency of their situation, as their presence can then be ascertained with proportionate certainty; but the relation of surrounding parts will affect the *safety* of an operation for extraction. Thus, when situated beneath the skin, although perhaps at some distance from the entrance-aperture; a bullet is readily detected and removed by an incision, care being taken to steady the ball lest it slip away out of reach. On the other hand, when the foreign body is situated deeply, and possibly already out of reach; its detection is less certain, unless a leaden bullet, by Nélaton's probe, and its extraction, in any case, by operation, is less safely accomplished. If, therefore, the body so placed, cannot be distinctly localized, or should it be inaccessible surgically, or both; the rule of practice suggested, is to abandon any further research, as well as any attempt at operative interference. This injunction becomes absolute in the case of a foreign body lodged in any internal organ.

An ordinary gunshot wound, presenting one or two, possibly more, openings, with an intermediate line of texture about to slough, is a kind of lesion which requires little or no external *dressing*. The apertures may be protected from exposure to dirt by corresponding pieces of wet lint; but any *restrictive* dressings which would preclude the escape of sloughs and the discharge of pus, are altogether at variance with the suggestions of pathology. An irregular and lacerated wound, externally, as by a piece of shell, may need such dressings to readjust and retain the textures in *position*.

6. The accompanying *inflammation* and tension with severe pain, are perhaps best moderated by warm water fomentations; but the choice of warm or cold and evaporating applications, must be guided by experience and trial in each case, rather than by any pathological considera-

\* This bullet extractor was used most successfully in the Franco-German war. An American invention, adopted by Weiss.

FIG. 46.\*

tion at present known. *Early and free incisions* may be requisite to relieve tension and thence the accompanying constitutional disturbance, and to give free vent to matter which otherwise accumulating would burrow and disorganize the part. This relief of tension will also limit the sloughing. Subsequently, the process of healing by granulation and cicatrization, guides and regulates whatever slight assistance may then be necessary on behalf of reparation.

Of the *untoward* events to which a gunshot wound, in general, is liable; *secondary* hæmorrhage is one. It is especially apt to occur when the sloughs loosen and separate—about the fifth or sixth day. At that time, therefore, the application of a tourniquet around the limb, in readiness to be tightened at a moment's notice, will always be a judicious precaution, but only as a temporary measure to arrest the hæmorrhage. Ligature of the bleeding vessel or vessels is imperative, and without delay. This should be done *in situ*, if possible; or when impracticable, then by ligaturing the main trunk; or *that* failing to command the hæmorrhage, amputation is the only resource. The probability of *gangrene* supervening, and thence the propriety of amputation; and the question whether it should be primary or secondary, are subject to the same or analogous considerations as with regard to contused and lacerated wound, and to compound fracture or dislocation.

7. *Amputation*.—The following *conditions* are said to require amputation; and with destruction of the whole substance of a limb, there can be no question as to the propriety of primary amputation:—

(1) If the limb be completely crushed and disorganized, whether by a direct blow or by wind contusion, though still left adherent; or, if the principal vessels and soft parts be carried away, though the bone be uninjured; or when the whole limb is carried off, a ragged stump merely being left.

(2) In some of the more serious injuries of the lower extremity, amputation is especially necessary. Thus, if a bullet divide the femoral vessels, or the sciatic nerve, and splinter the thigh bone; or if the sciatic nerve and soft parts at the back of the thigh be carried away, although the vessels and bone be left uninjured; and generally, all compound fractures of the lower part of the thigh. Amputation of the upper two-thirds of the thigh, for gunshot injury, is generally fatal. On the other hand, such injuries rarely *recover*. *Six* cases, however, and in the upper third, are reported to have occurred during the Crimean war. (Longmore.)

(3) Gunshot fracture of the bones of the leg, if the tibial arteries be injured, or if the knee or ankle-joint be wounded. In the middle of the leg, and if there be no longitudinal fissuring of the bone into either joint; the removal of splinters of bone may suffice.

(4) Gunshot wound of the foot, extending into the tarsus, requires amputation at or above the ankle; while analogous injury of the hand, often allows some operation of partial removal, reparation being more active in the hand than in the foot. Thus, three or four fingers with, perhaps, their metacarpal bones may be amputated, and a remnant-hand or thumb-hook be preserved.

(5) In gunshot injuries of joints; those of the upper extremity do not generally demand primary amputation; those of the lower extremity are more urgent. If the head, neck, or trochanters of the femur be splintered into the articulation by a bullet wound; death with or without

amputation, at the hip-joint, is about equally inevitable. *Excision*—as also in some cases of compound dislocation—is a more safe compromise. Bullet wound of the knee-joint, is a case for amputation rather than excision; but a similar wound of the ankle-joint, is, more frequently, an appropriate condition for excision. Bullet wound of the shoulder or elbow-joints, are conditions in relation to which excision is, yet more frequently, a promising substitute for amputation. Thus, 13 out of 14 cases of excision of the shoulder were successful in the hands of M. Baudens. Of 12 cases of excision of the shoulder-joint, 2 were fatal; in 17 of the elbow-joint, 2 only were fatal; and in 5 partial excisions of this joint, all were successful. Such, according to Mr. Thornton, were the results in the British Army during the Crimean War. In the Russian Army, according to Messrs. Mouat and Wyatt's Report, of 20 elbow-joint excisions, 15 recovered.

In duly considering whether amputation should be primary, or *secondary*—to give the limb *its* chance; the large proportion of unfavourable or fatal results of secondary amputation, must ever be taken into account. During the siege of Sebastopol, there were 3000 amputations, among 80,000 wounded Russians. Of the primary amputations of the upper extremity, of the lower and middle third of the thigh, of the leg, and foot, about one-third recovered; but of all the secondary amputations, more than two-thirds died. These results are more than corroborated by those in previous wars. Thus, primary amputation was successful in three-fourths of the cases, under Larrey, during the Napoleonic Wars; whereas, of 300 secondary amputations, reported by Faure, after the battle of Fontenoy, 30 only were successful. In the Peninsular War, the loss after secondary amputations of the upper extremity, was, as compared with the primary, as 12 to 1; and of the lower extremity, the loss was three times as great.

The general treatment—hygienic and medicinal—in relation to gunshot wounds, is the same as, under similar circumstances, with regard to other contused or lacerated Wounds, Compound Fracture, and Dislocation. Hygienic measures are chiefly important, and they claim special attention in Military Camp Hospitals; where, owing to the contingencies of warfare, regimen, ventilation, and general cleanliness, are more than usually liable to be defective.

## CHAPTER XVII.

### MORBID CICATRICES.

MORBID CICATRICES are either failures of reparation in the healing of Wounds, or various conditions of its results—in the form of faulty cicatrices. They comprise:—(1) Deficient cicatrix; (2) Excessive cicatrix; (3) Painful cicatrix; (4) Ulceration, Growths, and Degenerations of Cicatrix.

(1) *Deficient cicatrix*.—A thin, flat, shining, reddish, easily wrinkled and cracked scar, remains, commonly, after the imperfect healing of a weak ulcer or scrofulous sore. Such a condition depends obviously on deficient reparative power of cicatrization.

*Treatment*.—Pencilling with nitrate of silver, sulphate of copper, or other stimulant application, and protection of the surface from any external occasion of inflammation or injury; constitute the most probably

successful topical treatment. Any causative constitutional condition may be less preventable or remediable.

(2) *Excessive, and exuberant or Cheloid cicatrix*.—An opposite condition to the preceding; this form of cicatrix is thick, more or less projecting, irregular, dense, and perhaps adherent. *Contraction* of such a cicatrix is not an uncommon character, and the force thus exerted may be so powerful and long continued, as to produce great displacement and deformity. This result usually follows cicatrization after a burn, particularly if it be deep and extensive. (See Figs. 47 and 48.)

*Cheloid* or exuberant cicatrix, is well defined, gradually rising, with a rounded border, and a smooth, level, or slightly convex, or sometimes centrally depressed surface. Its substance is always tough and firm, becoming more so as it grows older. At first, usually more vascular than even a recent healthy scar, and having a florid or purple tint; it gradually becomes paler as it becomes harder, and at length resembles healthy exuberant skin. In point of structure there is nothing peculiar; compact fibro-cellular tissue more or less completely developed or degenerate, and slightly vascular, is covered with a thin cuticle. The size of a cheloid growth is generally distinctive; rarely more than half an inch in thickness, or more than half an inch in any direction beyond the extent of scar in which it grows, the growth thus differs from a fibrous growth of skin which it nearly resembles. Exuberant cicatrix may arise from some local cause of irritation during cicatrization, or some more obscure cause of a constitutional character. The latter would appear to be the origin of cheloid cicatrix; considering its infrequency as compared with the frequency of wounds and scars, and that many such growths may appear in the same individual, and reappear in the scars of wounds made for their removal. Cheloid cicatrix may supervene on a completely formed healthy cicatrix, and even long after it has remained so; it grows slowly, and generally, after a long duration ceases to enlarge or diminishes, and it is liable to undergo degeneration and ulceration.

*Treatment*.—Strong stimulants, applied repeatedly, have some effect in dispersing an *excessive* cicatrix; apparently by inducing or favouring degeneration and disintegration of the already imperfectly developed fibro-cellular tissue, and thus facilitating its absorption. Further growth may at least be retarded or prevented in like manner. Iodine paint and mercurial ointments, will perhaps prove the most effectual of these applications. *Adhesion* of the cicatrix to subjacent textures and to bone, is best overcome by subcutaneous division, as was, I believe, originally recommended by Mr. Hancock. A cicatrix, hitherto intractable, will, when thus detached, contract, and not unfrequently close in rapidly. *Contraction* of the cicatrix—as after a burn—is more preventable than curable. Mechanical restraint by some form of contrivance adapted to the situation and extent of the ulcer, and applied as soon as the eschar is detached, will perhaps prevent the effects of contraction. Counter-extension, by similar means, in the direction of contraction, will less surely overcome its effects. But it may be necessary to continue such resistance for weeks or months; often taxing the ingenuity of the Surgeon, and trying both his perseverance and that of his patient. In accordance with pathology, the general principles to be observed are the following:—That scar-tissues seem rather to adapt themselves by changes of nutrition to the external forces brought to bear on them, than to be merely stretched by them; that, in however long a time, the natural course and tendency

of scars is to soften down to a greater resemblance to the natural parts in both structure and relations; and, that they are of low vital power, apt, therefore, to waste or ulcerate quickly under irritation, friction, or pressure, and are thus removable by absorption.

*Cheloid* cicatrix is removable only by excision, complete extirpation being necessary, and not even then a guarantee of non-recurrence; but a recurrent growth of this kind is not more intractable than the original one.

Plastic operations, planned according to the particular case, are available for the cure either of excessive or of *cheloid* cicatrix. The chief general rules for such operations may be thus stated:—That if the scar is to be removed, so as to bring healthy structures together for union in its place, no portion whatever of its substance should be left; that scar-tissues should not be used for the formation of flaps, or relied on for any speedy or sound union; that if the scar or part of it is to be included in any flap for sliding or transplanting, all the borders and surfaces of such flap intended for union should, if possible, be of healthy structure, and not themselves parts of the scar; and, that flaps should not be dependent on scar-tissues for their supplies of blood.

(3) *Painful cicatrix*.—Commonly arising from adhesion of the subjacent nerves to the skin or bone, and not attributable to bulbous enlargement of their cut extremities; the cicatrix of any wound may thus be painful, although most frequently that of a stump after amputation. Usually, the cicatrix-tissue is sound, but the nerves are subject to constant irritation or inflammation, varying with the mobility and movement of the part. *Neuralgic* pain, of an excruciating and paroxysmal character, is due rather to some constitutional cause affecting a cicatrix, still healthy in itself. This condition may supervene long after the cicatrix is completely formed, and has loosened from any subjacent adhesions in the natural course of healing.

*Treatment*.—Free subcutaneous section is almost sure to prove remedial, when the pain arises from *adhesion* of the cicatrix. It is readily accomplished by introducing a tenotomy knife from the centre of the cicatrix, which usually remains open as an intractable ulcer, and sweeping round the cicatrix, to beyond its circumference. In this way I lately succeeded in permanently curing a painful cicatrix over the projecting head of the astragalus, after Chopart's operation. I found it necessary, however, to remove a portion of the bone, in order to bring the margins of the ulcer together, and to divide the tendo-Achillis in order to prevent retraction of the stump and tilting forward of the astragalus as was the case before the operation. The result was, that the pain ceased and the ulcer healed over the stump, the tendon was permanently lengthened by gradual extension of the foot after operation, and the man walked well on the flat of the stump to the ground. This result was the more noteworthy and satisfactory, considering that, as a crucial experiment, I had previously divided the tendo-Achillis without any effect on the cicatrix. Neuralgic pain can only be cured, if at all, by constitutional treatment; chiefly by quinine, and careful regulation of the bowels. The topical application of aconitina will often temporarily allay this pain; a grain of the best preparation of the alkaloid to a drachm of lard, in the form of an ointment applied from time to time.

(4) *Ulceration*, and other morbid changes, *growths* and *degenerations*, affecting cicatrix-tissues, follow the same pathological laws as in other structures; and are amenable to the same *treatment*, accordingly.

## CHAPTER XVIII.

## BURNS AND SCALDS. LIGHTNING. FROST-BITE.

**BURNS and SCALDS.**—*Structural conditions, and Diagnostic characters.*—Formerly, burns were classified according to their different degrees of structural disorganization, as represented by, inflammation, suppuration, sloughing, and ulceration. Fabricius Hildanus, Boyer, and Dr. J. Thomson, observed only three degrees of disorganization; Heister and Callisen recognised a fourth; but Dupuytren\* was dissatisfied with this ground of classification, which regarded only the intensity of the burns, while the nature of the parts affected—the *textures* injured or destroyed—were altogether disregarded. He therefore superadded this kind of classification, by distinguishing burns according to their various degrees of *depth*, from the surface inwards to deeper parts.

Firstly.—Erythema, or simple reddening of the skin. Secondly.—Vesication, the cuticle being raised in blebs, filled with serum. Thirdly.—Incomplete destruction of the skin. Fourthly.—Complete destruction of the skin, extending down to and involving the subcutaneous cellular texture. Fifthly.—Conversion into eschars of muscles, nerves, vessels, and other soft-tissues to within a variable distance from the bone. Sixthly.—Charring and complete disorganization of the whole substance of the burnt part. Obviously, this classification recognises not only the various degrees of disorganization, beginning with erythema and ending with charring; but the various kinds of tissue—*i.e.*, *anatomical* differences—are also recognised as grounds of distinction. Thus may be enumerated, burns of the skin, and those involving the cellular texture, the muscles, nerves, vessels, and so forth.

The distinctions laid down by Dupuytren are, however, practically useless. *Deep* burns, to the fourth, fifth, and sixth degrees, extending successively through tissues having very different anatomical characters, are not attended with correspondingly different degrees of shock, they undergo the same process of reparation by sloughing and suppurative granulation, and with equal probability of recovery. It should also be observed that, as the textures successively destroyed by deep burns serve very different functions in the animal economy, the relative importance of such burns is not proportionate to the *physiological* character and importance of the parts destroyed. Nor again, is the Surgeon concerned with the *pathologico-anatomical* differences of burns. He estimates not the effects of heat on the body by observing the different degrees of disorganization produced in the various textures—that this eschar is yellow and hard, and that is black and brittle—as the geologist or mineralogist would examine specimens of igneous rocks. The insignificance of pathologico-anatomical differences—no less than those derived from anatomy and physiology—will become more clear, and the basis of the most exact and early diagnostic distinctions of burns be supplied, by observing, clinically, the functional disturbances pertaining to them, or their

\* *Leçons Orales de Clin.-Chir.*, 1832, tom. i. p. 423.

*pathology.* These lesions, indeed, afford an almost exceptional instance of the superior importance of this ground of diagnosis, as compared with that of clinical pathological anatomy—by virtue of physical and structural characters. [P. ch. ii.]

*Superficial* burns are most important, and in proportion to the *extent* of surface affected, but not necessarily destroyed structurally. The more superficial the burn, the more the skin alone is affected, if only extensively; the more urgent will be the constitutional disturbance, and the more dangerous is the burn. A negro employed at the Bains Vigier, in Paris, wishing on one occasion to warm his limbs, which were benumbed with cold during a rigorous winter, immersed himself in a bath heated to a high temperature. In a short time he experienced a general feeling of uneasiness with acute pain in the skin. He was immediately withdrawn and carried to the Hôtel Dieu, where he expired in thirty-six hours! It is reasonable to suppose in this case, that although the water was heated to a high temperature, yet it was not at the boiling point, and that it acted only as a general rubefacient, without raising or destroying the cuticle; and yet here was a burn of only the first degree, but very extensive, and therefore accompanied with a shock to the nervous system, so sudden and overwhelming as soon to have proved fatal.

*Deep* burns, when not superficially extensive, are of comparatively subordinate importance; their significance having reference generally to the remote consequences of such burns, namely, exhaustion by sloughing and suppurative discharge.

*Causes, and their effects locally and constitutionally.*—Heat applied to the body is necessarily the cause in all cases; but it may have been either by fire, as by the clothes catching fire, the explosion of gunpowder or other explosive compound; or by means of a hot or scalding fluid, as boiling water or molten lead. The lesions produced in the former way are commonly designated *burns*; in the latter way *scalds*. This distinction is of practical consequence; burns not unfrequently resulting from the more prolonged application of heat, are deeper lesions, but perhaps of less superficial extent; scalds resulting from the more momentary application of heat, are more superficial, but generally they affect a larger extent of surface. Any adhesive fluid, as boiling oil, is a more persistent cause, and boiling perhaps at a higher temperature than water, it affects the tissues to a greater depth, as well as superficially. Some such fluids, clinging to the surface, run over a yet greater extent. Thus, then, scalds may be even more severe than burns; both by the *duration* of the cause, and the extent of lesion, superficially and in depth.

Explosive compounds are destructive, not only as causing burns of considerable extent, but also by the mechanical violence of their explosion, producing wounds which might be called *burnt* wounds, contused or lacerated. Grains of gunpowder, grit, mud, or other material, may, moreover, be introduced as foreign bodies into such wounds. Wounds of this kind were well marked in the persons of the unfortunate victims of the "Clerkenwell Explosion," admitted under my care into the Royal Free Hospital. In all cases, the wounds were not only contused or lacerated, and ingrained with dirt, as if portions of flesh had been gouged out by extremely forcible splashes of mud; but the surface of these wounds and surrounding integument, were apparently burnt, and contused by the concussive atmospheric force of the explosion. All the wounds sloughed for some time, with a yellow, and freely suppurating

surface; healing very slowly by granulation. The cicatrix subsequently contracted, and assumed a seamed, puckered appearance, notably in the wounds of the neck; just like the cicatrix presented by the healing of a burn.

Burns and scalds immediately induce pain and shock, both of which are more or less severe according to the superficial extent of lesion. The symptoms of shock, affecting the nervous system and circulation, are the same as those arising from any other injury. But it is accompanied with congestion of internal organs; the brain, lungs, and mucous membrane of the gastro-intestinal canal. The duration of collapse is variable, averaging about 48 hours—two days.

*Course and Terminations.*—(1) *Shock*, or *Congestion*, proves fatal in many cases within the first two days; and indeed of all the fatal cases of burn, a great majority die in this period. Mr. Erichsen collected 50 fatal cases, and Mr. T. Holmes 75 such cases, of burn; the former, with a view of determining the organs most frequently affected in each degree and period; the latter, with the special view of determining the mode and cause of death. 35 out of the whole 125 cases, died on the first or second day; but as the great majority of those who are thus burnt to death are not examined, the proportion is much greater than this. Thus, of 119 other cases brought to St. George's Hospital, 79 died in this period. In 16—Erichsen's proportion—of the 35 cases, the brain and its membranes were found congested, with more or less serous effusion into the ventricles or arachnoid, in 15 cases. The brain in the other case was not examined. In the remaining 19 cases, the brain was examined only in a few, but in 1 only was it healthy in respect of structure and vascularity. The thoracic viscera were congested in 8 of the 16 cases, and in 6 of the 19 cases; the congestion having passed into demonstrable inflammation in 1 of the former, and in 3 of the latter; thus making thoracic congestion in one-half the cases examined. The abdominal organs were somewhat less frequently congested; in 12 of the 16 cases, in 3 only of the 19. The mucous membrane of the pharynx and larynx, is extremely liable to be congested, apparently owing to the inhalation of flame or heated air during the accident; of the 19 cases collected by Mr. Holmes, which died in the first two days, some appearance of this kind was found in 13. The congestion in the pharynx very generally ceases abruptly at the commencement of the œsophagus; in some rare cases passing down into the stomach.

(2) *Reaction and Inflammation* constitute the next, or second period; extending from the end of the second day to the end of the second week. During this period, 25 out of the 50 cases died; and 29 out of the 75 cases; or 54 out of 125. The brain, lungs, and intestines, are the viscera principally affected; laryngeal cases usually die earlier. In the 25 cases, the brain was affected in 14; 11 being simple congestion, and 3 serous effusion. Of the 29 cases, the brain was not examined in the great majority; but in 3 it was congested, with effusion into the ventricles or arachnoid; but there was no evidence of true inflammation in any case. The lungs are more frequently affected. In the 25 cases, these organs were congested in 10 cases, and inflamed in 5. Of the 29 cases, inflammation of the lungs or pleura had occurred in 7 (in one of which, however, it probably existed before the accident), and congestion was noted in 5 others. The abdominal viscera—liver, spleen or kidneys—are perhaps never affected as a consequence of burns, except by pyæmia. But, the

mucous membrane of the gastro-intestinal canal, is usually inflamed, and probably ulcerated; with, in some cases, evidence of peritonitis. Inflammation followed by ulceration of the duodenum, is a notable occurrence, in the second period of burn, to which Mr. Curling first drew attention. In the 25 cases, ulceration of this portion of intestine was found in 6; in the 29 cases, in 4 of them; making a total of 12 such cases out of 54. In 3 more of the latter series, enlarged glands were found, in 1 of which cases, the glands of the whole intestinal tract were enlarged.

The *duodenal ulcer* is sharp-edged, and tolerably circular, as if a portion of the mucous membrane had been cut out; it is perfectly indolent, and usually situated just below the pylorus. Often there are two or three close together. Generally, the burn is on some part of the chest or abdomen. The earliest known period of duodenal ulceration is the fourth day; on the fifth day, it was noticed in 2 cases, and in 1 on the sixth. It usually occurs about the tenth day. This ulceration is unaccompanied by general inflammatory symptoms, or by any special symptoms. Persistent vomiting and bloody diarrhœa are the most reliable. Perforation of the bowel may ensue, and death take place suddenly from hæmorrhage, or from acute peritonitis. In one case, however, after death from other causes, at the end of eight weeks, a recent cicatrix was found in the duodenum.

(3) *Suppuration and Exhaustion, or Inflammation*, still prevailing, represent the third period; extending from the end of the second week to the termination of the case. The proportion of deaths at this period, was 9 in the 50 cases—less than  $\frac{1}{3}$ , and 27 in the 75 cases—more than  $\frac{1}{3}$ . Brain-lesions are accidental, being limited to infantile convulsions and pyæmia. The lungs or pleuræ are far more frequently congested or inflamed, and this condition is the cause of death. Thus, in 6 out of 9 cases examined in Mr. Erichsen's table—lesions of the lungs and pleuræ were noted. In 4 of these, the appearances were distinctly inflammatory; in the other two there was congestion with effusion into the pleuræ. Out of 27 of Mr. Holmes' fatal cases—during this period—the lungs were affected in 10, in 8 of which inflammation was the principal cause of death. Here, generally, the burn is situated on the chest. The symptoms—physical examination being precluded—are sufficiently marked; pain and oppression of breathing, hacking cough, and bloody expectoration. The gastro-intestinal mucous membrane is less frequently congested or inflamed; but ulceration of the duodenum is still not uncommon. Out of the 27 fatal cases referred to, in 6, open ulcers were found in the duodenum; in 1, a similar ulcer had undergone cicatrization, and in 1, the whole mucous membrane of the small intestines was inflamed but not ulcerated. In the other 9 cases referred to, no ulceration of the intestines was discovered. In 1 case only of Mr. Holmes' series, the jejunum and ileum were ulcerated, the duodenum being intact.

*Reparation.*—Burns and scalds undergo the same process of reparation, as similar lesions otherwise caused. But some features in their career are peculiar. Erythema, produced by a burn or scald, tends to subside, like any other simple cutaneous inflammation; resolution taking place with desquamation of the cuticle. Vesication also is resolved and terminates in like manner. Deeper burns involving, successively, the skin, subcellular tissue, and other adjacent textures; are followed by sloughing with the formation of eschars, abundant suppuration, and then the healing process of granulation and cicatrization. But the granula-

tions are exuberant, and the *cicatrix contractile*. At first thin, of a purplish colour, and shining, stretched, appearance; it immediately begins to contract, and contraction continuing for some months, with great and increasing force, the cicatrix gradually assumes a seamed and puckered

FIG. 47.

appearance; drawing together the surrounding parts, and ultimately producing strange deformity. Thus, remarkable distortions of the face and neck (Fig. 47), or of the joints are produced (Fig. 48).

FIG. 48.

*Tetanus*, *pyæmia*, *erysipelas*, and other affections may be omitted in estimating the causes of death as from burn; they being, rather, accidental concomitants.

The *period of death*, varies. The most fatal period is, perhaps, the

first week after the accident. Erichsen found that in 50 fatal cases, 33 terminated before the eighth day; 27 of these dying before the fourth day. Of the remaining 17 cases; 8 died in the second week, 2 in the third, 2 in the fourth, 4 in the fifth, and 1 in the sixth week.

*Prognosis.*—The chief considerations which determine the prognosis of burns and scalds, are—the more or less superficial character of the lesion and its extent, its situation, duration of the cause, and the age of the patient. The first two of these indications were sufficiently noticed in connexion with diagnosis; a *superficial* but *extensive* burn is far more unfavourable than a deeper and limited one. Hence many scalds are more fatal than burns. These indications, however, have reference to death principally by shock or congestion, in the first period, after burn; or by reaction and inflammation, in the second period. The *depth* of a burn—as compared with a scald—is significant with reference to suppuration and exhaustion, terminating fatally, in the third period. Deep burns are also unpropitious with regard to the part affected; distortion and loss of function supervening.

The *situation* of a burn, more especially indicates the probability of visceral congestion. Thus, burns on the chest or abdomen, are especially dangerous in relation to congestion of the lungs, or gastro-intestinal mucous membrane, respectively. Burns of the scalp are not so ominous of cerebral congestion; but they are specially unfavourable as regards the liability to erysipelas. The *duration* of the burning cause is, perhaps, favourable, as to the less liability of internal congestion or inflammation ensuing, but unfavourable so far as it implies a considerable depth of burn and consequent exhaustive discharge. *Age* has scarcely any relation specially to the prognosis of burns. Children are peculiarly liable to the danger of (secondary) visceral affections, cerebral, thoracic, and abdominal; and more easily succumb to their influence than adults. Extreme age is, of course, always comparatively unable to resist the shock, and consequences of injury.

*Treatment.*—(1) *Shock* and the tendency to *Congestion*, require immediate attention. Wine, brandy, ammonia, are the stimulants commonly administered to induce reaction. Warm tea may be sufficient, if the patient be young and the burn slight. Laudanum, in favour with some Surgeons, is, I think, undesirable, as being conducive to congestion. (2.) *Reaction*, occasionally excessive, must be moderated by any gentle depletory measures, otherwise than by loss of blood. Mild purgatives and the withdrawal of stimulants for a time, will generally reduce any undue reaction, as measured by the pulse and heat of the skin. It should ever be remembered that any temporary tendency to *inflammatory* symptoms, readily subsides into a congestive tendency, affecting the internal organs. (3.) *Suppuration* and *exhaustion*, are specially inevitable in the course of deeper burns; although some exhaustion supervenes in all burns. The strength of the circulation should therefore be retained for this period; and maintained when it arrives. Stimulants are again required, with tonics, and the generous diet suitable in cases of profuse and prolonged suppurative discharge arising from any cause.

*Local treatment.*—The primary indication is, protection of the surface from exposure to the action of the air. Increased and persistent pain and shock will thus be prevented. Various topical applications are used protectively, and sometimes indiscriminately.

The degree or depth of burn, will, I think, best determine the choice.

*Erythema*, or vesication, cannot require any application more than simply protective. "Carron-oil," consisting of equal parts of linseed oil and lime water, answers admirably. Lint, dipped in this thick, yellow, pul-taceous fluid, forms a covering, at once exclusive of atmospheric influence and emollient. Deeper burns, destroying the cuticle, skin, and so forth, thus presenting an exuding surface, are perhaps more advantageously covered with some absorbent material. Flour, dredged over the surface soon forms an encrusting artificial skin. This need not be removed until loosened by increasing discharge and separation of the eschar. The removal of this crust by the Surgeon would be attended with great pain, and damage to the surface about to heal, and would aggravate the constitutional disturbance. But, the possibly irritating character of this kind of dressing, and the impossibility of removing it, without these evil consequences, are serious objections to any such application. Cotton-wadding wrapped around the part forms a good protective covering, and aids in restoring the temperature of the part, a consideration of importance in proportion to the extent of surface involved; but this application alone is objectionable for the same reasons as the flour-dressing. Carron-oil dressing, enclosed it may be with cotton-wool, is, generally, the most eligible application.

The ulcer formed by the detachment of the eschar, must be treated agreeably to the general directions already given with regard to Ulcers. Water-dressing, or a weak solution of nitrate of silver, will then be appropriate, according to the state of the granulations. Pencilling the marginal granulations with nitrate of silver or sulphate of copper, may be necessary, to repress their exuberant growth, and favour cicatrization. No dressing in the whole course of treatment, should be reapplied unnecessarily; its removal being attended with great pain, and much increasing the constitutional disturbance. One of my earliest recollections as a student, was that of witnessing the shrieking of a patient during the dressing of a large burn over the thorax and abdomen, the muscles quivering and bleating by exposure to the air.

*Contraction of the Cicatrix* is the grand difficulty to be prevented or overcome. In anticipation of this event, Dupuytren recommended attention to position and the application of counteracting mechanical contrivances, as soon as the eschar had become detached and during cicatrization. But any such adjustment of splints and bandages or other apparatus, will generally prove effectual only for a time; the cicatrix contracting when left free, and at length presenting its usual appearance and the accompanying deformities.

*Operations*, therefore, are practised with the view of overcoming contraction. *Division* of the cicatrix has often been tried, but with little permanent success. Complete division is necessary, both as regards the extent and depth of the cicatrix, any subjacent bristles must also be freely divided. All contraction having been thus overcome, extension should be maintained mechanically during granulation and cicatrization in the lines of incision. With every precaution, however, the new intervening cicatrix-tissue is apt to acquire the same evil disposition. I have had recourse to this operation in many cases, and repeatedly in the same case; but with no more successful results than in the hands of other surgeons. *Transplantation* of a flap of healthy skin into the gap made by division and extension of the cicatrix. This proceeding is far more generally successful, permanently. Very happy results have been attained by Teale, Mütter, and James in thus overcoming the deformity occasioned

by burns of the face and neck. Eversion of the lower lip into the chin, a disfigurement attended with slobbering peculiarly revolting, may be remedied by Teale's operation. The everted lip is divided into three equal parts, by two vertical incisions, each three-quarters of an inch in length, and carried down to the bone. These incisions are so placed that the middle or intervening portion occupies one-half of the lip. From the lower end of either incision, another is carried upwards to a point one inch above the angle of the mouth. The two flaps, thus indicated, are freely and deeply dissected up. The alveolar margin of the median portion is then pared. The lateral flaps are raised, united by twisted sutures in the middle line, and supported as on a base by the median flap, to which they are also attached by a few points of suture, leaving a triangular even surface to granulate. Gradual extension of the cicatrix from the sternum, and elevation of the chin can be accomplished by means of a screw collar devised by Mr. James.

*Diseased conditions of the cicatrix* have received sufficient attention in this work among Morbid Cicatrices, in general. Erichsen notices particularly a projecting red and glazed cicatrix, looking as if composed of a mass of fungating granulations smoothed down and lightly skinned over. This warty cicatrix—observable after burns about the neck and chest, more especially—resembles cheloid growth, but is remarkable as being the seat of intolerable itching, not relieved by any external application. Large doses of liquor potassæ mitigate this distressing symptom. But, if small and narrow, the cicatrix may be dissected out; if large, it does not admit of removal without risk of considerable hæmorrhage, as the structure, though fibroid, is very vascular.

*Amputation* is an operative resource unavoidable in certain external cases. Complete destruction, by charring, of the whole substance of a limb, leaves no alternative; or, as a secondary operation, it may become advisable under circumstances, locally and constitutionally, analogous to those resulting from other forms of injury.

LIGHTNING produces effects, locally, in the direction of its course through the parts, resembling the appearances of an ordinary burn; but the shock may suspend the functions of the nervous system, partially or generally, without any marked appearances of burn, and may thus also kill instantaneously.

A *stroke* of lightning affecting the brain, knocks down the individual with loss of consciousness; lasting from a few minutes to a longer period, in one case an hour and a quarter. Recovery shows that paralysis was suddenly produced, partially or completely; and this state may continue for an indefinite period. The special senses are variously affected; loss of sight, smell, hearing, and taste; or more rarely, exaltation or perversion of these functions may have occurred. Hæmorrhage from the mouth, nose, or ears, sometimes happens; and abortion in some cases. A remarkable effect is said to be produced occasionally; the formation of an image, as if photographic, of neighbouring objects on the body, even on parts covered with clothes.

Every degree of *burn* may be produced, and perhaps in the same person, from the slightest singeing of the hair, reddening or blistering of the skin, to the deepest charring. Other incidental injuries may occur, but rarely, such as wound, or fracture, particularly of the skull. The tongue was mutilated in four out of six cases of injury recorded by M. Bondin.

The *prognosis*, partly guided by the same considerations as with regard to Burns, is generally more favourable respecting the local lesion, which may be comparatively trivial, and also in respect to shock. But the subsequent paralysis or other functional disturbance may be a specially unfavourable condition, as consequent on a stroke of lightning not immediately fatal. Some persons seem to have *premonitory* symptoms of the approach of a thunderstorm. One such individual, within my own knowledge—a remarkably robust young man—is invariably troubled with extreme nervousness, headache, and an indescribable dread, compelling him to go to bed some hours before any apparent approach of a storm. How far this might be an unfavourable state of the nervous system is unknown.

*After death* by lightning, certain appearances are remarkable if not characteristic. The attitude of the body may be that in which it was when struck, or the body may be thrown to some distance from the spot. Rigor mortis, occasionally absent, is commonly present, and well marked, or even to an intense degree of rigidity, resembling the condition of a person frozen to death. The blood, sometimes coagulated, is usually singularly fluid, and continues in this state. Decomposition is sometimes speedy, but often delayed. The clothes are generally burnt or rent, even when the body is intact.

The *Treatment* of suspended animation from a stroke of lightning consists in artificial respiration, with warmth and stimulants to restore the circulation.

**FROST-BITE.**—Cold, intense or long continued, produces effects analogous to those of heat. It may kill the part directly, a local destruction analogous to charring, and accompanied with depression of the nervous and vascular systems, analogous to shock; or the part dies by the speedy supervention of gangrenous inflammation, a process of destruction accompanied with inflammatory reaction as the constitutional disturbance. Unlike heat, cold more frequently kills by its direct operation; presenting the condition known as frost-bite. This local effect, moreover, frequently exceeds in importance the concomitant general depression of the system.

The *local* condition may therefore be taken first in order. The symptoms are—loss of sensation and power of motion in a muscular part; and, the circulation becoming arrested, a remarkable pallor overspreads the surface, deadening into a stone colour, with stiffness increasing to hardness, and even brittleness of the part, when quite dead.

The *constitutional* disturbance arises principally from general exposure of the body to cold, under the circumstances of frost-bite. Languor, and an overpowering sleepiness, ending in stupor or coma, invariably supervene during prolonged exposure to severe cold, and may thus cause death, the part itself dying with the general failure of life. The whole body becomes frozen by more continued exposure, and thence the condition known as “frozen to death.”

A part frozen or frost-bitten is not irrecoverably *dead*. A whole limb may have become perfectly insensible and cold as ice, white and transparent like marble, incapable of being bent without breaking; and yet not absolutely dead. The combs of cocks and the ears of rabbits were frozen by Hunter, but these parts afterwards recovered. Leeches and frogs have been placed in the same state and then restored to life. Cold-blooded animals, and parts of warm-blooded animals, when frozen, are,

therefore, not dead, but asleep as it were, and can be aroused ; even as a seed is ready to sprout, awaiting circumstances favourable to life. How long a frozen part or animal may retain its susceptibility of life is uncertain ; but this is certain, that unless reaction be gradual, the returning flow of blood is apt to become excessive—to pass into inflammation, speedily ending in gangrene. While, therefore, gradual and moderate elevation of temperature induces salutary reaction and restoration, sudden or immoderate accession of warmth will inevitably excite gangrenous inflammation.

*Treatment.*—In the dormant state of any part of the body from frost-bite, when although apparently dead the part is recoverable, pathology suggests the solicitation of reaction short of inflammation ; and thence the prevention of gangrene with loss of the part.

Restorative reaction can only be accomplished by the moderate and gradual application of warmth. Friction with something of nearly the same temperature as the frozen part, fulfils this two-fold indication ; and thus, rubbing the part with snow is a practice both surgical as well as popular. A tingling or burning pain, and purplish redness, announce the returning circulation and tendency to inflammation.

Gangrene having supervened, the separation of the slough should be left to Nature ; any unnecessary interference would give a fresh start to the process of destruction, in textures reduced to a low state of vitality.

Amputation may become necessary, as after a burn ; the operation being performed also in point of time and situation, after the formation of the line of demarcation and above it.

## CHAPTER XIX.

### CELLULITIS. CARBUNCLE, AND BOIL.

CERTAIN Blood diseases are declared by local inflammations of the subcutaneous cellular texture.

*CELLULITIS.—Structural Condition.*—The textural changes wrought by this inflammation are these :—Speedily an effusion of serum engorges the subcutaneous tissue ; this being soon exchanged for a purulent, bloody, sanious fluid. The cellular membrane dies rapidly, appearing in the form of shreds and skeins, and as mats of wet tow, or like large wads of wet shammy-leather ; extending over a whole arm, a whole side, or over both, successively. An immense extent, therefore, of cellular texture is sacrificed, and this wide-spread subcutaneous slough passes in between the neighbouring muscles ; but the fasciæ are singularly spared ; thus the tendinous septæ between the ribs are seen bared in places where the muscular substance itself and all other textures have disappeared. This process of destruction probably involves the skin, and to a corresponding extent. Yet vesicles or bullæ seldom appear until the subcutaneous inflammation is very far advanced. These vesicles are in general solitary, sometimes remote from the cellular disease, of considerable size, and occasionally filled with bloody serum

*Symptoms, and Diagnosis.*—Cellulitis might be mistaken for erysipelas. The swelling is not unlike,—in both diffuse and œdematous. But the pain is at once the earliest and most distinctive symptom ; it is excru-

ciating. This, without perhaps any, even the slightest blush of redness, is characteristic of cellulitis. And should the skin become involved, the cutaneous inflammation is always *secondary*, in all cases of true cellulitis; by advance from below upwards, from the cellular texture to the skin. This latter texture remains uninfamed, or is not primarily and essentially affected.

*Fever.*—The fever which precedes and accompanies cellulitis, aids but little to establish an early and exact diagnosis. In those cases which Duncan observed, this fever had so much of the typhoid type, that it was scarcely possible to foresee which disease would be eventually declared. Nevertheless, the fever presented considerable varieties in respect of its symptoms and progress. It sometimes commenced insidiously, sometimes turbulently, but in most of the severe cases soon reached its height. Its chief peculiarities were; the supine position with depressed shoulders, in which attitude the patient almost always lay, without turning to either side, the absence of coma, and the rare occurrence of delirium. The respiration was often remarkably embarrassed, owing to the inspiratory muscles,—pectorals, intercostals, &c., being the seat of cellulitis. In some cases, dyspnoea was rendered more urgent by pleurisy. In others, the respiration was itself much affected, especially when the disease began in the arm. Certain facts of apparently minor significance, because only occasional, are; a peculiar cadaverous smell emitted from the patient's body during life; in one case, a fœtid and coloured sweat proved critical.

*Blood origin.*—Two facts at least point to the inference that cellulitis is the local manifestation of a blood-poison.

The fever being *typhoid*, resembles the working of some blood-poison analogous to that which is undoubtedly in operation when typhoid fever is engendered by "infection;" and the local manifestation itself—cellulitis being a "serpiginous" inflammation—extending continuously, and not confined to one spot, shows that some morbid condition of the blood disturbs the course of textural assimilation.

*Blood-pathology.*—The nature of the blood-poison is wholly unknown. The best account of this disease is given by Dr. Duncan.\*

*Treatment.*—*Preventive* measures are unknown, nor can they be discovered until the etiology of this disease is better understood. The *remedial* treatment, so far as art has any controlling influence, is substantially the same, both constitutionally and locally, as for phlegmonous erysipelas.

CARBUNCLE and BOIL are alike, essentially, inflammations of the subcutaneous cellular texture, which may occur in various parts of the body; but the effusion is *circumscribed* and brawny, so that the imprisoned cellular tissue invariably sloughs. Certain differences are worthy of notice.

CARBUNCLE or ANTHRAX is a flat, oval or circular, somewhat spongy swelling, having a brawny circumscribed border; the whole swelling being of a dusky, reddish-brown colour, and very painful,—burning, contracting or throbbing. The size of this swelling varies from half-a-crown to that of a dinner-plate, and it varies also with the progress of the inflammation. Increasing slowly, at length the skin over the flat surface, sloughs at numerous points, forming as many small apertures, through which a greyish sloughy and purulent, fœtid discharge oozes, or starts

\* Trans. Med.-Chir. Soc. Edin., 1824, vol. i.

up on the slightest circumferential pressure; presenting a cribriform appearance never to be forgotten when once seen, peculiar to carbuncle. As sloughing of the skin advances, the apertures run together and coalesce, the cribriform surface disappears, and discloses the subjacent cellular texture, a quagmire of slough. Carbuncle is commonly situated about the shoulders or on the nape of the neck, where if large it gives a remarkable breadth to that part. Occasionally occurring on the lower part of the back or sacrum, it may form on the front of the chest or abdomen, sometimes on either extremity, and very rarely on the forehead or face. One on the nose, seen by Sir B. Brodie, gave the most singularly hideous appearance, completely disguising any lineaments of the human face. Fortunately, carbuncle is usually solitary.

*Fever* of the typhoid character precedes and accompanies the swelling, and it becomes more marked as sloughing ensues. But there is also a notable derangement of the liver and other digestive organs, indicated by a yellowish complexion and brown furred tongue.

The *causes* of carbuncle are, as to their essential or pathological nature, obscure. It is a disease of advanced years, or it occurs in those whose constitution has broken down prematurely. It is also induced by habitual free living, without exercise. It is associated, not unfrequently with diabetes mellitus or albuminuria; and swellings of a carbuncular character are not uncommon in some infectious diseases, as typhus and typhoid fevers, and plague.

*Course and Terminations.*—Generally, the slough of cellular texture having been thrown off or removed, the cavity, often of considerable size, slowly heals by suppurative granulation; and the patient's health is ultimately regained, a marked improvement having taken place when the slough was detached. But the brawny induration remains for some time, and a puckered cicatrix permanently. Sometimes, however, the sloughing deepens as well as extending superficially; and involving important subjacent parts, or overwhelming with prostration, thus proves fatal. A large carbuncle situated on the nape of the neck is especially perilous. Rarely, a carbuncle subsides suddenly, and the person rapidly sinks. A remarkable instance of this mode of fatal issue, is related by Sir B. Brodie.\*

The *prognosis*, in different cases, will be guided by the foregoing considerations.

*Treatment.*—*Preventive* measures are said to be occasionally successful. In the earliest stage of the disease locally, while yet only "a small pointed vesicle on a hard, brawny base," observes Mr. Erichsen, its further progress may often be completely arrested by opening the vesicle and rubbing its interior with a pointed stick of potassa cum calce or nitrate of silver. Later still, he has often seen the extension of a carbuncle prevented and a cure effected, by covering it with a square of soap-plaster spread on thick leather, with a hole in the centre for the exit of discharge. I have had no experience of a carbuncle in this stage, nor of the preventive treatment accordingly. *Curative* Treatment consists chiefly in a certain operative proceeding. The preservation of as much integument as possible, by the limitation of sloughing, with the relief of pain and constitutional disturbance, are primarily important; and the discharge of slough subsequently is equally so. Early relief of tension fulfils the

\* Pathology and Surgery, 1846, p. 393.

former indications, an outlet fulfils the latter. Timely, free incisions, fulfil both. A *crucial* incision, carried through the slough and the surrounding induration, answers admirably. The *period* for making this double incision, must be determined by due observance of both the purposes in view; always inclining to the consideration of relieving tension. A free application of potassa fusa, after the bistoury, was recommended by the late Professor Miller, in order to at once form an eschar and thus limit sloughing. Poulticing until the slough is discharged, and then dressing according to the state of the ulcer, are the only applications ordinarily required.

The constitutional treatment, medicinal and dietetic, much resembles that of phlegmonous erysipelas. Early recourse to stimulants, tonics, and a generous diet; but with special attention to the state of the liver and digestive organs. Yet here we encounter the chief difficulties. Inappetency, nausea or actual sickness, and mal-assimilation, all conspire to defeat our alterative mercurials and effervescing salines, as well as our endeavours to coax the stomach with digestible and nourishing food. If any other disease, to wit, diabetes or albuminuria, be associated with carbuncle, such complication will further embarrass the treatment.

**BOIL or FURUNCULUS.**—In some of its external characters, Boil contrasts with Carbuncle. It is a *conical* swelling, softening as it matures, but set in a hard base; of a purplish red colour, and exquisitely painful and sensitive. Its *size* is much more moderate than carbuncle, never perhaps exceeding the smallest swelling of that kind, about half-a-crown. Its smaller size and conical shape are diagnostic, even in an early stage. Enlarging slowly, matter forms at the apex of the cone, tipping it with a yellow colour; this point bursting, at length discloses a subjacent slough or core of cellular texture. But, the cribriform, flat, surface of carbuncle is never seen,—another diagnostic difference. Like carbuncle, a boil is commonly situated where the skin is thickest; on the back of the neck, shoulders, or the buttock, a favourite spot of election; occasionally in the arm-pit, or on the thigh. They always seem to choose the most troublesome situations. To increase the torment, they seldom come singly, but are gregarious or successive.

*Feverishness*, generally of a more sthenic character than with carbuncle, accompanies the formation of boils.

The *causes* also, so far as they are known, somewhat differ from those of carbuncle. Usually occurring in earlier life, boils are also connected with a plethoric state of the system; but they may denote an enfeebled condition, or they may appear in the sequel of febrile diseases. Their fitful character is often far less explicable. Active exercise by persons of sedentary habits, sea-bathing, the spring-time of the year, or some epidemic influence, will, perhaps, severally suffice to bring out a crop of boils.

The *treatment* is that of carbuncle on a small scale. A poultice or warm fomentation, to promote suppuration and detachment of the slough, should be followed, if the latter does not take place, by a sufficient incision for expulsion of the core without any thumbing or squeezing. With water-dressing, the little granulating wound will then look after itself.

Constitutional measures must have reference either to the plethoric or debilitated state of the system. Alterative mercurials and saline aperients, followed by liquor potassæ and other alkaline treatment; or quina, iron, and nitro-muriatic acid, the acid-tonic treatment.

**CHILBLAIN.**—This is a local inflammation of the skin, of an asthenic type; and subject, perhaps, to regular recurring attacks of congestion. It occurs in three degrees:—(1) Simple congestion, attended by great itching, alternating with periods of extreme tenderness to external pressure; (2) or, in the form of vesication; (3) death or sloughing of the affected portion of skin, and perhaps of the sub-cellular tissue, forming an ulcer of an indolent character.

The *Symptoms* of chilblain are obvious, in connexion with each of these forms of this affection. Congestive purplish-redness, with a tingling, itching, or burning heat or pain, which comes and goes, and some degree of swelling which has a shiny appearance. Recurrence of the symptoms seems to be determined by circumstances affecting the circulation, as exposure of the part to the warmth of a fire, or of a periodic character, as the stimulant effects of daily meals. The vesicated and ulcerated forms of chilblain present appearances which are sufficiently indicated by these terms. Certain parts of the body are most commonly affected; the feet, hands, or both; more rarely, the lobes of the ears, or even the end of the nose.

The *causes* of this affection may be said to be, sudden variations in the external temperature, and in connexion with the predisposing condition of a weak circulation. Hence, chilblain is liable to occur in persons of the leucophlegmatic temperament, or of a scrofulous constitution. Age has decidedly some influence; it happens most frequently in young persons or children, and of both sexes; and in adult females more often than in men. This liability generally passes off towards manhood; and chilblains are rarely met with in men over forty years of age, though in weakly women they may recur throughout life. Local causes affecting the free circulation in the part, should not be overlooked; such as tight gloves, elastic bracelets and garters, tight shoes, the sitting posture, long continued, in cold rooms, with the legs pendant.

*Treatment.*—*Preventive* measures will consist in promoting the general circulation; by an even temperature, particularly as regards sleeping and sitting rooms in cold weather, warm under-clothing, socks and gloves, with regular exercise; and, the removal of any restraint to the circulation in exposed parts of the body. A generous diet, with small stimulant doses of opium and quinine, may likewise prove salutary. In the event of any chill, affecting particularly the feet and hands, the circulation should be restored very gradually, by frictions and warmth. *Curative* treatment consists, when chilblains are unbroken, in bringing the congestive inflammation to resolution, by daily frictions with stimulating embrocations, as of camphor or tincture of iodine, and soap liniment. The old-fashioned remedy, brandy and salt, should not be despised. Intolerable itching might, perhaps, be relieved by lead-lotion, or opiate ointments. Vesicated chilblains may be protected by a coating of collodion and castor-oil varnish. Ulcerated chilblain must be treated by poulticing rendered stimulating by admixture with spirits of wine, or turpentine, until any slough separates; and then the dressing may be resin-ointment, or other topical applications, as for any other weak or indolent ulcer.

**WHITLOW OR PARONYCHIA.**—An asthenic inflammation of the dense fibro-cellular tissue forming the pulp of the finger or thumb; this part becomes acutely painful, tense and hard, swollen so as to give a globular appearance to the end of the finger, and of a reddish colour (Fig. 49). The inflammation and swelling are always diffuse—unlike phlegmon; and

it tends also to suppuration and sloughing of the cellular texture,—thus also differing in its termination. Necrosis of the ungual phalanx is not an uncommon event, in prolonged cases. Whitlow occurs spontaneously in persons of a naturally weak or of a debilitated constitution, affecting both

FIG. 49.

young and old, and either sex. Occasionally, it appears to have an epidemic character, arising in many persons without any traumatic cause; and perhaps at certain seasons, as in the spring. But it arises frequently from some local irritation, as a puncture, scratch, or inoculation with some poisonous matter. Hence, it is more frequently met with in connexion with certain occupations, as in cooks, washerwomen, and grooms.

Whitlow, involving the *sheath of the tendons*, is a more severe form of this affection. It is attended with greater swelling of the whole finger, extending to the hand, which becomes much puffed and enlarged. Shooting pain up the arm, and more violent throbbing with suppuration, are experienced; but the redness is not proportionate, and the end of the finger, particularly if the cuticle be thick, and the palm of the hand hardened by work, may assume a dull-white appearance—soddened, perhaps, by poulticing. Some inflammation of the lymphatics, denoted

by red lines extending up the arm, not unfrequently accompanies this form of whitlow, and with much low feverishness or constitutional disturbance. Diffuse suppuration soon takes place in the sheath of the tendons, and may even spread up the fore-arm, under the annular ligament. The swelling has an elastic character, but distinct fluctuation is obscure. Sloughing ensues, not only of the cellular texture of the finger and hand, but also of the tendons and palmar fascia. Necrosis of the phalanges results; or a matted state of the part, with a rigid and contracted state of the finger and perhaps of the hand, rendering the part useless.

*Treatment* is primarily, the prompt employment of repressive measures; by leeching, poulticing, and an elevated position of the hand. In the *simple* form of whitlow, a crucial incision into the pointed swelling of the pulp of the finger, should be made at an early period; or even snipping the vesicated summit will give great relief. In the *tendinous* form of whitlow, early, and free, longitudinal incisions, along each side of the finger, must be had recourse to, for the relief of tension and swelling. The digital arteries should be avoided, and the sheaths of the tendons not opened,—to prevent sloughing, and rigidity of the finger ensuing. Then well soak the finger, and hand, in warm water, and envelope the whole with a poultice. The nail, which growing and elongating, may appear large, often loosens, and should then be removed by evulsion with a small pair of sequestrum-forceps. Otherwise, as a foreign body, it would be a source of continued irritation. Any adherent portion need not be removed, but the remainder of the nail may be pared and scraped. A new nail will form, if the matrix be healthy; probably taking a period of five or six months, before it is completely restored. In tendinous whitlow, when the inflammation has subsided, a pasteboard splint will be advisable, to prevent contraction.

*Necrosis* of the unguis phalanx will necessitate the extraction of this dead portion of bone; leaving the pulp end of the finger and nail, which eventually form a somewhat hooked extremity, tolerably sensitive and useful, and not so unsightly as a truncated end. Amputation will be unavoidable, in the event of more extensive destruction, involving the middle, or the first, phalanx. And it is better to operate rather, apparently, too high, than too low for the sake of preserving a useless remnant of a finger; any portion of the thumb, however, will be most useful. The general health must be renovated by tonics and diet.

ONYCHIA is a form of ulceration, which commences about the matrix of the finger-nails. It usually arises from a pinch or crush of the finger end, bruising the matrix or loosening the attachment of the nail. Shortly after this injury, the finger-end swells, and fluid is effused beneath the nail, which loses its natural colour, and becomes thin and flattened at the end, or more rarely curled up laterally. As the nail continues to grow, it turns upward and exposes beneath it, a very foul, fætid, and painful ulcer; while the finger-end becomes enlarged and bulbous, the integument hardened, shining, and of a livid red colour. This affection occurs mostly, according to Mr. Thomas Smith's observations, in children under ten years of age; but that it is by no means common. It is little prone to spontaneous recovery; proceeding, perhaps, to necrosis of the unguis phalanx. The disease is sometimes named *onychia maligna*, as a *specific* ulceration.

*Treatment* is firstly, evulsion of the nail; and this is accomplished either by tearing it off as a whole by seizing it with a narrow-bladed pair of sequestrum-forceps; or, by dividing the nail with a narrow-bladed pair of scissors, run up to the root of the nail, and then everting each half with the forceps. Both scissors and forceps must be applied with a firm hand. Local anæsthesia will suffice to completely deaden sensibility—the pain otherwise being excruciating. Pounded ice and salt mixed in a bladder is convenient for this purpose, or Dr. Richardson's ether spray is equally efficacious. Water-dressing or carbolic lotion may then be followed by arsenical solution—one or two drachms of the liquor potassæ arsenicalis, to an ounce of water. Chlorate of potash and tonics, especially bark, complete the treatment.

*Syphilitic* onychia, as a secondary affection, has already been noticed.

IN-GROWN TOE-NAIL.—This is a not uncommon condition, among especially the working-classes; it may occur on either side of the great-toe nail, but more frequently on the outer side. It is attended with considerable pain in walking, and gives rise to fungoid and sensitive granulations, overspreading and concealing the in-growth, accompanied with a thin, fætid discharge. This condition is caused apparently, either by overcrowding the toes in a narrow, hard boot, thereby thrusting the adjoining integuments over the side of the nail; or, by the toe-nail having been pared away too deeply at the side, thus allowing the integument to overlap; in either way the nail grows into and includes itself in the overhanging fold of integument. *Treatment* consists in removing any cause of pressure, as a tight, or hard-toed boot, and then endeavouring to correct a faulty growth of the nail. The pressure of the integument on the nail may also be relieved by neatly inserting shreds of oiled cotton-wool into the cleft by means of a probe on the back of a scalpel-blade. Then, when sufficiently separated in the course of some days, the margin of the nail may be gradually raised in like manner, until the natural state of the part is restored. Scraping the edge of the nail very thin may prove to be

sufficient relief; or, by notching the free edge down to the matrix, the strip of nail as it grows, may gradually overlap the body of the nail, and thus bring relief. Any obstinate or deep in-growth can only be cured by evulsion of the nail, as in the treatment of onychia. After any such mode of cure, the fungoid granulations will subside, or they may be repressed by pencilling with nitrate of silver or sulphate of copper. Zinc ointment may be applied during the healing.

**CORNS.**—Local hypertrophy of the cuticle forms the common corn; a flattened or conical swelling, hard or soft, often acutely painful—varying in this respect, according to pressure on the part, the state of the health, and even the weather. Such cuticular out-growths occur commonly on the feet, usually on the outer aspect of the end of the little toe; or between the toes, and then always as a soft corn, apparently from maceration of the cuticle by warmth and moisture. Occasionally, corns form on the hands, and more rarely over the prominences of the elbows or knees. They are produced by intermittent pressure or friction on some naturally prominent part, as on the little toe, by wearing a tight, hard boot. Eventually, beneath an old corn, a bursa is apt to form, which, becoming inflamed from time to time by pressure, greatly aggravates the pain and inconvenience in walking. Suppuration is liable to occur.

*Treatment.*—Relief is obtained by simply removing the cause of pressure. Wearing a loose shoe or slipper, or protecting the corn by means of a circular plaster of thick leather, having a hole in the centre over the corn. Thus, the common “corn-plasters” are used. Pencilling with nitrate of silver induces desquamation, and thus thins down the corn. Paring or scraping down the corn previously macerated in warm water, will also give relief, as occasion requires. Extraction of the centre or core of the corn, is the ordinary practice of chiropodists. But the full-grown corn is liable to return. Inflammation and suppuration must be treated on ordinary principles.

**Horns.**—Remarkable forms of out-growth, consisting of fibrous or fibro-cellular texture, are liable to occur on various parts of the body; springing from the various sebaceous cysts, unruptured, or ruptured spontaneously or by accident. Similar kinds of out-growth may arise from the matrix of one of the toe-nails, especially the great toe; extending from one to four inches in length, tapering at the point, and curved spirally like a ram’s horn. This is simply a vertical elevation of the epithelial layers forming the nail.

*Excision* completely from the base of the horn is the only cure.

**WARTS or VERRUCÆ** are collections of overgrown cutaneous papillæ, either completely ensheathed by an excessive production of scaly epithelium, or with the papillæ isolated, each having only its own natural cuticular sheath. They may occur in various parts of the body, a common situation being the hand and fingers. Warts may arise spontaneously, apparently, or be congenital, or perhaps hereditary; but usually they proceed from some source of local irritation—as dirt or discharge, or from the handling of animal matter, in cooking or dissection. They occur in girls who have the evil habit of masturbation, though the presence of warts on the hands should not alone beget an unworthy suspicion of such practice. Venereal warts, excrescences, or vegetations, well illustrate the origin of warty growths from irritative discharge. Such and similar warts are undoubtedly contagious. Common warts come and go, sometimes, in an unaccountable manner.

*Treatment.*—Escharotics may succeed in removing these often obstinate out-growths. The strong acetic acid, applied by means of a glass-brush, or rod, is the most efficacious. Excision with the knife or curved scissors, is the only other mode of cure.

**MORBID GROWTHS.**—Besides Warts and the other cutaneous out-growths already referred to, the skin may be the seat of tumours or morbid growths—*e.g.*, painful subcutaneous tubercle, nævus, epithelial cancer. (See Ch. II.)

**ULCERS.** (See Ch. IV.)

## MUSCLES AND TENDONS.

### CHAPTER XX.

#### SPRAIN.—RUPTURE.—TUMOURS.

**SPRAINS OR STRAINS.**—*Structural Condition, and Symptoms.*—Muscular and tendinous structures are liable to be suddenly stretched by violence, without any actual or perceptible rupture of fibre. This lesion commonly occurs to those muscles which are most apt to be brought into action by any sudden and violent exertion, as in running, leaping, dancing, or lifting a weight. Immediate pain and inability to use the part, followed by stiffness, are conclusive symptoms. Any degenerative change, or softening of the structure, will predispose to this kind of injury. It may be succeeded by atrophy and partial paralysis.

*Treatment.*—Rest is necessary for reparation, and this requisite is secured by the renewal of pain from any attempt to use the damaged muscle or tendon. Subsequently, friction and stimulant embrocations aid in overcoming the stiffness and removing any remaining thickening.

**RUPTURE OF MUSCLE AND TENDON.**—This lesion may be regarded as only a further degree of sprain, but it presents certain additional particulars of importance.

The part of the muscle or tendon ruptured is in the muscular substance, the junction of the muscle and tendon, the tendon, or the junction of the tendon and bone. In twenty-one cases Sédillot found the rupture had occurred at the junction of the muscle and tendon in thirteen, but through the muscle in eight only. Occasionally, the sheath of the muscle or tendon is ruptured; a protrusion taking place through the aperture. This more frequently occurs to the long head of the biceps muscle, or the extensor tendons of the fingers. The muscles most liable to sprain are also subject to rupture, by sudden and violent exertion. Hence the gastrocnemius, or its tendon; the quadriceps femoris, just above the patella, of which I have seen two instances—the biceps and triceps of the arm; the former giving way above, in its long head, or below, at its insertion, the latter muscle or tendon rupturing just above its insertion into the olecranon. More rarely, the deltoid or the pectoral muscle yields, the rectus abdominis, or the muscles of the back.

The *symptoms* are generally well marked; sudden pain and powerlessness, with a sensation as if something had given way, and perhaps an

audible snap. Pain is far less acute if a tendon be ruptured. An interval may be discovered in the situation of rupture, into which the finger will fall when passed over the surface; a hard swelling above and below is also felt—the retracted muscle, if its substance be the seat of rupture. Subsequently, this state of the part is obscured as inflammatory swelling supervenes, or reparative lymph occupies the interval between the ruptured ends of muscle or tendon. Some discoloration may accompany the former change, or any extravasation of blood incident to the injury.

*Causes.*—Muscular contraction is the immediate cause of rupture far more frequently than external violence. Age predisposes, by reducing the elasticity of muscular texture in common with that of all textures. Rupture, therefore, occurs most frequently in persons of middle life, and who are sometimes wont to undertake feats of sudden exertion beyond their strength, in running, jumping, dancing, or lifting a weight. Degenerative changes will also predispose; and thus the rectus abdominis muscle has been found to have undergone fatty degeneration in some cases of its rupture.

I am not aware of any such predisposing conditions having been noticed in connexion with the rupture of tendons.

*Course, and Terminations.*—(1) *Reparation* ensues, and readily, in most cases. It has been traced by Paget and Adams in rabbits, and by the latter observer in the human subject. The process is the same, essentially, and alike after subcutaneous division or rupture, as follows:—

Separation of the ruptured extremities of a *tendon*,—*e.g.* tendo-Achillis, takes place to a very variable extent; in an adult, from one to two inches, in an infant, about half an inch. The upper portion is drawn upwards, proportionately to the contractile power and contraction of the muscle, and the lower portion is drawn downwards, proportionately to the mobility of the ankle-joint and position of the foot. Similar or analogous circumstances limit the separation of the divided extremities of tendon in all cases. The separated ends still remain indirectly connected with each other through the medium of the cellular sheath of the tendon, which remains almost intact, as a tubular sheath. Blood, in very small quantity, is generally effused within the sheath, and adheres to the upper and lower extremity of the tendon, principally to the upper. But if the blood be sufficient to fill the sheath and infiltrate the surrounding tissues, reparation is retarded, and rendered proportionately less perfect. It is an unfavourable incident. Increased vascularity of the sheath marks the commencement of the true reparative process; this vascularity extending to the subcutaneous cellular tissue and fat. Reparative blastema is effused into the meshes of the cellular sheath, as a matrix, which thus becomes succulent, as well as vascular; the infiltration may also extend into the surrounding cellular texture, and obscure the gap in the divided tendon. This blastema is developed into fibres, through the medium of oval nuclei; unlike inflammatory lymph in open wounds, which is developed into fibres through nucleated cells, transition forms being found in the shape of elongated cell-fibres. The nucleated blastema would seem to undergo transition by elongation of the oval nuclei, and their arrangement in parallel linear series; thus presenting a fibrillated, and ultimately more distinctly fibrous appearance, under the microscope. Capillary blood-vessels are formed in the connective tissue thus produced, and concurrently with the process of its development.

The divided ends of the old tendon take no active part whatever in the reparative process during its earlier stage, and have but slight connexion with the new material when first formed. A little later, their square surfaces and sharp edges become somewhat rounded, and their substance somewhat softened. Enlarging, and evincing a disposition to split; thin streaks of new material, greyish and translucent, are interposed; indicating the commencement of junction between the old and new tissues. The bulbous enlargement of the old tendon-ends, occasioned by the increasing interposition of new material, gradually subsides; until they regain their former appearance, and the new and old tendon become of uniform diameter. The appearance of fine dovetailing long remains, being distinctly traceable a year and a half, and three years, after division of the tendon. Complete and firm junction of the new with the old tendon is established; a want of definition along the deep surface of the new tendon, remaining permanently, owing to adhesion between this surface of the tendon and the deep fascia. Re-formation of a separable sheath on the surface of the new tendon, completes the process of reparation.

The new tendon, homogeneous rather than fibrous in appearance, is at first vascular and ruddy, but afterwards greyish and translucent; an appearance contrasting with the old tendon, above and below, and which is retained up to the latest period of examination hitherto made in the human subject, or three years after operation. Considerable toughness and strength is soon acquired; in the tendo-Achillis of a rabbit, six days after its division, a weight of 20 lbs. was required to rupture it, and after the lapse of ten days, the rupturing weight had increased to 56 lbs. A linear cicatrix is supposed by Mr. Tamplin, and other observers, to be the ultimate remnant of the bond of union; but, according to Mr. Adams' observations, this appearance is deceptive, the connective tissue or new tendon remaining permanently, during life. The greatest *length* of new tendon formed in the human subject, is apparently, as Mr. Adams states, two inches and a quarter; and this was found in the tendo-Achillis of a girl, aged nine years, a year and a half after tenotomy.

Divided *muscles* undergo, essentially, the same process of reparation, union by a fibro-cellular bond.

*Treatment.*—Rest is of course requisite for union to take place; but attention to position by relaxation of the muscle or tendon, and the maintenance of that position, are equally necessary, the structure being not merely strained or stretched, but divided. These indications of treatment are well illustrated by the treatment of rupture of the *tendo-Achillis*. The leg is flexed, and the heel drawn up, by means of a band attached to the shoe behind, and

FIG. 50.

fastened to a belt around the lower part of the thigh. (Fig. 50.) If the relaxed position be disregarded, the uniting bond will inevitably be elongated and weak. With this result, antagonistic muscles may afterwards occasion considerable deformity by their continued and inadequately opposed contraction. Talipes varus—after operation and premature removal of the splint—may thus become slowly converted into the opposite deformity,—talipes valgus. Hence also the newly united muscle or tendon should be exercised very gradually and cautiously.

(2) *Imperfect and non-union of Tendon.*—Various causes lead to these results.

*Imperfect union* of the tendo-Achillis, for example, may arise from, some constitutional defect in the reparative powers of the individual, or from depressed vital power in the limb, owing to paralysis. Injudicious after-treatment, from ;—not sustaining the temperature of the limb, especially in paralytic cases during very cold weather ; too early and too rapid mechanical extension ; too early exercise of the part.

*Non-union* is specially liable to arise, when tendons are situated in dense tubular sheaths ; the divided ends of tendon becoming adherent to the inner surface of the sheath, but not having any direct connexion with each other.

*Treatment.*—Any of the causes of imperfect, or non-union, must be avoided or corrected. With respect to mechanical extension, after operations for deformity ; Mr. Adams does not consider it necessary to make extension gradually, for the purpose of stretching the new tendon, the requisite length of which should be obtained during the period occupied in its formation, ordinarily, two or three weeks ; but gradual extension is necessary, either to overcome ligamentous resistance, or to prevent a too rapid and excessive separation of the divided ends, and thus regulate the length of new tendon produced. The liability to non-union may be avoided, by never dividing a tendon in its course through the denser portions of its sheath, and when the operation is performed near to such parts, extension should be conducted very gradually.

Certain operations have been practised to induce the reparation of an ununited tendon. Paring the ends and joining them by suture will seldom prove satisfactory. Subcutaneous puncture, as for ununited fracture, has proved successful in some cases.

**DISPLACEMENT OF TENDON** may occur. The tendon of the tibialis posticus muscle, occasionally slips out of its groove, with instant pain and lameness. The long tendon of the biceps flexor cubiti is sometimes tilted out of its groove. Such mishaps generally rectify themselves, the tendon slipping in again ; or replacement can be readily accomplished by a little manipulation.

**INFLAMMATION OF MUSCLE.**—Rare as a primary disease, the muscles may be involved by the extension of Inflammation from adjacent structures. Rheumatic inflammation of the muscles is probably of this kind, affecting primarily the investing aponeuroses. Syphilitic inflammatory indurations of muscle are also said to occur.

A notable instance of inflammatory extension I once saw ; peritonitis extending to inflammation of the abdominal recti muscles, which after death presented a quagmire of slough and pus. Immediately behind the sheath of these muscles, and near the umbilicus, lay the vermiform appendix of the cæcum, which contained a bean. It was, apparently, a grand effort of Nature to discharge this impacted foreign body.

The *treatment* of muscular inflammation must be conducted on general principles, having reference to the apparent causes in operation.

**TUMOURS OF MUSCLE**—Equally rare, perhaps, as primary diseases, the muscles are yet sometimes the seat of Morbid Growths. The reader is referred to the distribution of Morbid Growths, for some such particulars. But, Mr. Teevan has collected 62 cases of tumours of muscles. About one-third were *cancerous*; 16 *fibrous*; 8 *cystic*; 5 *hydatid*; and 5 *erectile*. Mr. Erichsen has seen 7 cases of tumours “primarily” formed in muscles. In 1 case, a fibro-cystic tumour, as large as a cocoa-nut, was “developed in connexion with the tensor vaginæ muscle;” in 1 case, a cystic tumour, the size of a foetal head, developed in the substance of the adductor brevis of the thigh; in 1 case, a *fibro-plastic* tumour, the size of a child’s head, formed within the sheath and in the substance of the sartorius muscle of the left thigh; in 1 case, another cystic tumour, about as large as a goose’s egg, springing from the flexor brevis digitorum. Encephaloid cancer formed in the cicatrix, and springing from the muscle just named, showed the nature of the original tumour. In two cases, the tumours were hydatid; one in the deltoid, the other at the outer edge of the latissimus dorsi. In the 7th case, the tumour was an *enchondroma* in the tibialis anticus muscle. In one other case, enchondroma was situated in the vastus-externus; and in yet another, it was connected with the pectoral muscle.

The muscles of the lower limb are most frequently the seats of tumours; in the upper limb, according to Mr. Teevan, the muscles usually, are the pectoralis major, deltoid, and biceps. Those of the neck and trunk are seldom diseased, excepting the rectus abdominis muscle, a frequent seat of tumours.

The *treatment* of muscular tumours differs in no way from that of the same growths situated in other parts of the body. Excision and amputation are the only known resources.

**DEGENERATION of Muscles**—see General Pathology and Treatment of Degeneration.

## BURSÆ AND SHEATHS OF TENDONS.

### CHAPTER XXI.

#### INFLAMMATION.—GANGLION.

**BURSÆ MUCOSÆ. SYNOVIAL BURSÆ.**—The bursæ are synovial sacs, resembling other synovial membranes, and differing only in situation. They are interposed—to facilitate motion—between the surfaces of parts which naturally move on each other. Thus, they are situated, normally, as sub-cutaneous bursæ, in the cellular texture between the skin and some firm prominence—*e.g.*, the bursæ over the patella; or deep-seated, between a muscle or its tendon and bone, or between two muscles or tendons, and not unfrequently communicating with a neighbouring joint. Subcutaneous bursæ may be adventitious, resulting from enlargement of the areolæ in the cellular texture by continued friction; as beneath corns, bunions, the prominent points of club-foot, and other exposed situations. Such bursæ

are, however, imperfect; spaces being thus formed in the cellular texture, rather than bounded by any true synovial membrane.

*Situations of Normal Bursæ.*—In the following situation, bursæ exist naturally, and are subject, therefore, to injury or disease:—behind the angle of the lower jaw, on the symphysis of the chin, on the angle of the thyroid cartilage, on the acromion, between the lower end of the scapula and the latissimus dorsi, under the deltoid, on the external and internal condyles of the humerus, the olecranon, the styloid processes of the radius and ulna, on the metacarpo-phalangeal articulations, their dorsal and palmar surfaces, and on the dorsal aspect of the phalangeal articulations; on the anterior superior spine of the ilium, the great trochanter, the tuberosity of the ischium, and under the gluteus maximus, on the patella, on each condyle of the femur, the tuberosity of the tibia, in the ham, on the two malleoli of the tibia, the os calcis, the dorsal surface of the toes, and the plantar aspect of the heads of the first and fifth metatarsal bones.

(1) *INFLAMMATION* of a bursal sac may occur, with enlargement and distension of the sac with synovial secretion. Suppuration soon follows, and the formation of abscess, which bursts externally or into the surrounding cellular membrane. This texture is also liable to become involved as the abscess progresses. The resulting ulcerations are singularly obstinate.

(2) *Chronic enlargement* of a bursa, from long continued pressure and irritation rather than inflammation—is another condition of common occurrence. The bursa becomes distended with contents of variable nature, partly fluid and solid; as an increased sero-synovial secretion of clear straw-coloured fluid, or a brownish fluid, thick and grumous, apparently due to altered blood, or adhesive and containing cholesterine. Fibrinous matter is occasionally deposited on the interior of the sac, gradually producing considerable thickening of the wall of the sac. Within the sac, numerous small flattened and elongated bodies may form, resembling melon-seeds or parboiled rice; and which result, apparently, from disintegrated fibrinous matter subjected to motion and attrition, or from the detachment of pedunculated fibrinous matter from the interior of the sac. The origin and production of these bodies is thus similar to the formation of loose cartilages in joints, and they gradually acquire a fibro-cartilaginous character. Lastly, fibrinous deposit progressing concentrically, may at length convert the bursa into a solid tumour, having a laminated structure, or leaving a small central cavity containing a gelatinous fluid.

The *diagnostic character* of these various structural conditions is tolerably obvious. Inflammation, followed by suppuration and abscess, sloughing and ulceration; will be severally attended with their usual signs and symptoms.

Enlarged bursæ are chronic indolent tumours; with distinct fluctuation, denoting fluid contents, or having a solid resisting character according to the deposition of fibrinous matter. Thickening of the sac forms a semi-solid tumour, and the production of melon-seed-like bodies sometimes yields a crackling sensation on handling the sac, while complete solidification presents a hard elastic tumour.

*Causes.*—Some local injury, as pressure, friction, or a blow, is generally the cause, whether of inflammation or simple enlargement of a bursa. Occasionally, some constitutional tendency seems to have a predisposing, or possibly productive influence.

*Treatment.*—*Inflammation* may be subdued by rest, cold or warm fomentations, and topical bleeding. Suppuration having occurred, a free opening must be made and poulticing continued until granulation is established. *Chronic enlargement* of a bursa yields to various methods of treatment according to the nature of its contents. An accumulation of serous fluid in the sac may be absorbed by a stimulating application, such as iodine paint, which I prefer. By puncturing the sac and pressure, or by the injection of iodine, adhesion may be induced; or the introduction of a seton for a few days may lead to suppuration and contraction.

Fibrinous matter having been deposited, thickening of the sac, and an accumulation of melon-seed bodies within its interior, may possibly be cured by a seton, inducing discharge and contraction. But this condition, or that of complete solidification, generally necessitates removal of the bursa surgically. When fairly dissected out, the disease can never return, and commonly no evil consequences follow this operation. In one case only, after I had thus extirpated an old enlarged bursa patellæ, phagedænic gangrene appeared in the wound, and spread to some distance above and below the knee. But this was, evidently, an accidental concurrence, and no valid objection to the method of treatment.

**PARTICULAR BURSAE.**—*Bursa Patellæ.*—The bursa situated over the patellæ is liable to the same diseases as those common to all bursæ. *Inflammation* and its consequences, or simple chronic enlargement, not unfrequently occur. "Housemaid's knee," as it is called, is an inflammatory affection of the bursa patellæ; arising from frequent pressure and irritation by kneeling on a hard surface. But the same condition may be produced in other females and in males, under similar circumstances.

*Caries* of the patella—consequent on abscess of the bursa—possibly involving the knee-joint eventually; seems to be the only pathological peculiarity worthy of notice in connexion with this disease.

The *treatment* is the same as that of bursal affections in general; the treatment of inflammation and suppuration; or, in a chronic state, stimulating applications, puncture and pressure, injection, a seton, or extirpation by careful dissection, having regard to the proximity of the joint to the enlarged bursa.

*Bunion.*—Inflammatory enlargement of the bursa situated on the inner aspect of the metatarsal bone of the great toe, or of an adventitious bursa formed in that situation, is the essential element of a bunion. The sac contains an increased quantity of thin serous fluid, or a dense crystalline secretion occasionally, as observed by Sir B. Brodie and M. Boyer. Over this enlarged bursa, a corresponding portion of thickened and horny cuticle, a large corn forms; both of which constitute the bunion. (Fig. 51.) The toe is generally displaced obliquely outwards, lying over or under the adjoining toes; thus forming an angle more or less obtuse at the metatarso-phalangeal articulation, or root of the great toe, and considerably increasing the prominence inwards. Acute pain, redness and heat—the symptoms of inflammation—accompany this swelling; it being partly an inflammatory enlargement of the bursa.

FIG. 51.

*Chronic bunion* represents the result of this state, inflammation having subsided into a tolerably painless enlargement of the bursa; but which is liable to become acute, occasionally.

The *cause* of this condition is the pressure of a tight and narrow-pointed boot or shoe, habitually worn; whereby the toe gradually becomes turned outwards from its natural direction, increasing the pressure on the root of the toe projecting inwards. The formation of bunion is, therefore, mostly secondary to, and the consequence of, this displacement of the toe. Continued and increasing pressure thus bearing on the root of the toe, the bursa there situated enlarges or a new one is produced, and the superimposed cuticle becomes a corn.

The *course* of bunion is apt to be very destructive. The internal lateral ligament yields under the constant strain, suppuration within the bursal sac frequently supervenes, the abscess slowly progressing to the surface and opening by a small circular aperture in the centre of the horny callosity; or destroying the ligament and involving the joint; the cartilages are eroded, the bones become carious, and partial dislocation inwards is permanently established.

Some relief of the intolerable pain and of the other inflammatory symptoms, follows any evacuation of matter; but an indolent and unhealthy sore remains, indisposed to heal.

*Treatment.*—Removal of the cause in operation is primarily important. A large shoe should be worn, or one with a compartment for the great toe, so as to keep the toe in a line with the metatarsal bone, and thus relieve pressure. By a contrivance of Mr. Bigg, the toe can be drawn inwards. A compress of thick soft leather, spread with soap-plaster, and cut in the form of a horse-shoe, or a circular piece with a hole in the middle, may be applied; the opening corresponding to the bunion, which is thus relieved from pressure. Inflammation is to be overcome by the usual topical applications: poulticing or cold lotions according to the state of the bunion. Abscess forming in the bursa, an opening should be made without delay, both to relieve the intense pain and prevent any destruction of the joint.

*Chronic bunion* is best removed by painting it with a strong solution of nitrate of silver. A large, and perhaps painful cyst, may be destroyed, as recommended by Sir B. Brodie and M. Boyer, by an incision into the sac, and cauterizing its inner surface with nitrate of silver or nitric acid. It should be observed whether the sac communicates with the joint. Destruction of the internal lateral ligament, and the articulation, may terminate well, by fixing the joint with a gutta-percha splint; or this condition may necessitate excision or amputation of the toe. The latter operation has been resorted to successfully, in some cases.

*SHEATHS OF TENDONS.*—(1) *Tenosynovitis—acute and chronic.*—Sheaths of tendons in the neighbourhood of joints, are most liable to inflammation. The flexor and extensor tendons of the wrist, for example, are subject to strains in various laborious occupations. To guard against any such injury, it is not uncommon for navigators and others similarly employed, to wear a band around the wrist, as a support to the tendons.

Puffy swelling and some pain in the course of tendons, after injury, denote inflammation of their sheaths. A peculiar creaking, jerking, sensation and sound, is elicited on moving the part. This latter sign differs from the true crepitus of fracture.

The *treatment* is in no way peculiar. Rest, and warm fomentations;

followed by stimulant applications and pressure in the chronic state of inflammation. Blistering, embrocations, and a bandage are thus efficacious; or the emplastrum ammoniacum cum hydrargyro employed as strapping, is both stimulating and supporting to the part affected.

(2) *Ganglion*.—This is a simple or barren cyst or sac, attached to, but communicating with, a sheath of a tendon. It contains a firm, transparent whitish, gelatinous matter, resembling the vitreous humour of the eye. The cyst varies in size and shape, from a pea to a filbert; and presents a corresponding tumour, smooth, elastic, moveable, and subcutaneous; situated usually on the back of the wrist, occasionally on the dorsum of the foot. This little tumour is itself painless, even when pressed firmly under the thumb, although the patient experiences a sense of weakness in the joint.

*Chronic ganglion* does not so much increase in size, as the cyst attains considerable thickness and resistance. Arising from a sprain, or as it were spontaneously—unlike a subcutaneous bursa which proceeds from pressure—ganglion is usually of slow growth, but, sometimes, makes its appearance quite suddenly.

*Compound Ganglion* is described by Erichsen, as a dilatation of the sheaths of the tendons; often attaining a very considerable size, and usually becoming irregular in shape, several tendons being implicated in it. Often the sheath is thickened as well as dilated, and highly vascular, being lined with a red, fringed, and velvety membrane; the contained fluid is clear and yellowish, but usually thinner than in simple ganglion; or the fluid may be dark and bloody, containing masses of buff-coloured fibrine or a large number of granular bodies, like those met with in enlarged bursæ. “These bodies are composed of perfectly developed granulations, in which the remains of blood-vessels are visible, probably thrown off from the inner wall of the vascular sheath.” Compound ganglion is chiefly met with in the palm of the hand, and on the dorsum, sole, or inner side of the foot. This form of the disease is extremely *chronic*, may acquire an almost malignant appearance, and occupy a very extensive surface; in one case, the dorsum and greater part of the inner side of the foot were involved. Simple ganglion, however, in this situation is larger, flatter, and less moveable than on the back of the wrist. In some instances, Mr. Tatum has seen such a ganglion, on the outer part of the back of the foot, more than two inches in diameter and compressed.

*Treatment*.—*Simple ganglion* is, usually, amenable to remedial measures. In its ordinary situation, on the back of the wrist, a ganglion may be dispersed by squeezing it with the thumbs, or by a blow with the back of a book; the sac bursting and evacuating its contents under the skin. A *chronic ganglion*, having a thickened sac, may require considerable pressure before it yields, and the sac remaining may still give the appearance of a ganglion; deceiving both the operator and the patient, unless the sensation of bursting be noticed during the application of pressure. Sometimes, the cyst refills, and it may be necessary to continue pressure by means of a compress and roller, firmly applied. Occasionally also, other measures as for an enlarged bursa, are requisite; puncture and pressure, a seton, or extirpation by dissection.

*Compound ganglion*—distension of the sheaths of tendons—is a far more obstinate disease; especially, when occurring in its usual situation, the palm of the hand. The sheaths of the flexor tendons are distended, containing a glairy or other fluid. The elastic tumour, thus formed,

beneath the palmar fascia, extends under the transverse ligament into the forearm, in the form of a double swelling, constricted by the ligament. The fingers are contracted. The treatment by free incision of the tumour, dividing the annular ligament, and healing from within, as recommended by Syme, may be advisable, although apparently an extreme measure. But other proceedings; the passage of a seton from above under the annular ligament into the palm, or the injection of iodine, are more hazardous, as methods of treatment by inducing inflammation.

## NERVES.

### CHAPTER XXII.

#### INJURIES.—NEURITIS.—NEURALGIA.

**INJURIES.**—Nerves are seldom injured alone, but in connexion with other textures, the injury being shared in common with them. Nerves are, however, liable to similar lesions as other soft textures; wounds, incised, punctured, and contused, and to contusion without breach of continuity. Perhaps, the latter lesion is the most frequent, as when the ulnar nerve at the elbow is contused by an accidental collision, just catching the nerve in its course between the inner condyle and olecranon.

The symptoms attending these forms of injury vary with the amount of injury to the nerve, and its own functional importance. Pain, tingling or other perverted sensation, accompany contusion; complete paralysis of sensation, and of motion, in the parts supplied by the nerve, denote division. This has happened in excision of the elbow-joint; division of the ulnar occasioning immediate loss of sensation on both sides of the little finger and inside of the ring finger, with inability also to move these fingers. Sometimes, loss of temperature, and failure of nutrition supervene; owing probably to the loss of nervous influence on the circulation in the part to which the nerve is distributed.

Fortunately, restoration after contusion, and reunion, after division, not unfrequently take place; the nerve sooner or later resuming its functions.

The *treatment* will, therefore, be guided by these considerations. Rest in all cases, and apposition of the ends, if the nerve be divided.

**NEURITIS.**—Inflammation of Nerve.—*Symptoms.*—Pain, severe and continued, shooting along the nerve or nerves affected; and rendered intolerable by pressure in their course, or on attempting to move the part. Jerking of the muscles often occurs. Some heat and swelling along the course of the nerve may perhaps be detected, if the inflamed nerve be situated near the surface. Marked inflammatory fever is present in all cases. *Chronic* neuritis is attended with a subsidence of all these symptoms, leaving the nerve still sensitive, and sometimes painful; and the individual worn out by suffering and sleeplessness.

*Causes.*—Usually arising from injury; the various lesions to which nerves are liable may induce inflammation, extending along the sheath of the injured nerve. But neuritis may also proceed from some blood-poison, of which it is the local, or one of the local, manifestations.

Sciatica is probably a manifestation of this kind; a rheumatic inflammation of the sciatic nerve.

*Treatment.*—Local blood-letting and warm fomentations are most suitable in neuritis of traumatic origin. Rheumatic neuritis must be treated, locally and constitutionally, as acute or chronic rheumatism.

NEURALGIA.—*Symptoms, and Diagnosis.*—Pain is still the essential symptom as in neuritis. It may be even more severe, or excruciating, but it is paroxysmal; shooting along the course of a nerve, or diffused, but commonly relieved by firm pressure, although generally induced by the slightest superficial touch or movement of the part. Various anomalous sensations may be experienced, as creeping, tickling, or burning in the part. Spasm of the muscles is a frequent concomitant. Slight heat, puffiness, and redness may supervene, and increased secretion, as of tears or saliva when the nerves of the eye or jaw are affected. But no fever of an inflammatory character accompanies the attack. Its duration is usually much shorter than neuritis; lasting perhaps only a few minutes, although prolonged indefinitely in some cases. The periodical return of neuralgia, at a certain time in the day, or in certain months of the year, is also characteristically distinctive.

From structural disease of the part, neuralgia is distinguished by the absence of any special physical signs—*e.g.*, inflammatory swelling, and of fever; and also by the character and disproportionate severity of the pain. From hysterical pain, it differs in mostly being restricted to one part, and by the absence of general hysterical symptoms.

The association of structural disease with neuralgia is sometimes most perplexing. But here—and with regard to hysteric pain—the diagnosis may be determined by the aggravation of the pain by deep pressure, rather than any marked cutaneous sensibility. The mistaking structural disease for neuralgia, would mislead the treatment; but this error is not so seriously misleading as the mistaking neuralgic pain for structural disease. By attention to the foregoing points of distinction, the line may generally be safely drawn between neuralgia and disease of the joints, the breast, testicle, and other parts.

Certain nerves are more frequently the seat of neuralgic pain. The divisions of the fifth pair are specially liable; and in particular the supra-orbital branch. But neuralgia may occur in perhaps any part of the body; in the scalp, ear, nose, back of the neck, the back, chest, abdomen, arms, ball of the thumb, legs, feet.

*Causes.*—*Constitutional* conditions, mostly of an obscure character, seem to be the essential cause of all this suffering. A generally depressed state of the nervous system, and circulation of the blood, may be said to represent the constitutionally causative condition, usually apparent. Thus, constant exposure to wet and cold, the climatic influence of damp localities, or periods of the year, depressing passions, not unfrequently induce neuralgic attacks in persons previously healthy. Certain blood-poisons are less obvious, but not less potent. The malarious poison of marshy districts, is thus sometimes the source of the most severe and persistent neuralgia. Chlorosis from amenorrhœa is another such cause. The influence of blood-conditions may be even more conspicuous, in albuminuria; a disease in the course of which, I have witnessed neuralgic attacks of more intense agony, than in any other disease. *Local* irritation is often the immediate and exciting cause. A carious tooth, or piece of dead bone elsewhere, the accumulation of scybalous matter in the

intestinal canal, or other sources of irritation, centric or eccentric, are causes of this kind. The pressure of a tumour in the course of a nerve, or a neuromatous tumour itself, would sometimes appear to be causes of neuralgia; but any injury to, or disease of the nervous system, is in this sense causative. Dr. Pemberton suffered for many years from excruciating pains in his face, to relieve which, Sir A. Cooper severed the three divisions of the fifth nerve, on different occasions, without avail. Driven from practice, and worn out by protracted suffering, at length death brought that release which art had failed to give. A tumour was then found in the brain; and thence the origin and persistency of the pain endured during life. Similar instances of *sympathetic pain* are cited in the work on "Principles," p. 674.

*Course and Terminations.*—Neuralgia is as uncertain in its subsequent history, as its pathology and etiology are obscure. The attacks may cease suddenly, leaving the individual in apparently good health, or soon to recover from the temporary exhaustion consequent on pain and sleeplessness. Or the sufferer at length succumbs, dying from sheer exhaustion.

*Treatment.*—The cause or causes in operation must be diligently sought for, in each case. It will be useless, however tempting, to remove a merely local cause, when the constitutional condition is still in operation. A change of residence from a damp or malarious locality, may thus be necessary. Other depressing circumstances already noticed, are less under control. *Medicinal* treatment may, however, do something, preventive or curative. Quinine, in large doses—two, three, five grains, or more, will sometimes ward off an attack or cut it short. Quinine treatment continued in smaller doses, sometimes proves curative. Preparations of iron, the sulphate in particular, are more effectual in neuralgia of malarious origin. In albuminuria the blood restorative action of iron, is counteracted by the constant retention of urea and other excrementitious matters in the blood. Disordered menstruation must be remedied by the administration of emmenagogues—*e.g.*, galbanum, myrrh, &c., in conjunction with tonic treatment. Constipation or irregular action of the bowels, by aperients, chosen according to the occasion. Thus, aloetic purgatives, rhubarb, mercurials, and salines, are all useful, in different cases.

Any *local* cause of irritation must not be overlooked, but its removal will seldom overcome a true neuralgic tendency. The extraction of a carious tooth, for example, seems only to divert the recurrence of pain to another, and possibly sounder tooth. Local applications—sedative or counter-irritant—are comparatively useless. Belladonna, opium, aconitina, and other powerful sedatives have been tried in vain. The hypodermic injection of morphia is, perhaps, more promising. Blistering, or instilment embrocations, will rarely be tolerated by the patient.

*Section of the nerve* is a last resource. It cannot succeed in cases of neuralgic pain depending on pressure in the course of a nerve, unless the occasion of pressure can be detected, and the operation be performed above that part. It was thus unavailing in the case of Dr. Pemberton. When appropriate, the section must be an *excision* of a portion of the nerve, the simply divided ends otherwise regaining their continuity.

NEUROMATOUS TUMOUR.—See Morbid Growths.

## ARTERIES.

## CHAPTER XXIII.

## INJURIES OF ARTERIES.—ANEURISM.

WOUNDS—and of SPECIAL ARTERIES.—These Injuries are conveniently associated, respectively, with WOUNDS in general (Ch. XIV.); and with TRAUMATIC ANEURISMS in various parts of the body. (Ch. xxiv.)

ANEURISM.—*Structural Conditions.*

—Aneurism may be generally defined to be a collection of arterial blood communicating with an artery, from which it has arisen. (Fig. 52.)

This collection of blood may be *circumscribed*, commonly, by enclosure within a dilated portion of the artery, as a sac, forming *true aneurism*; or possibly within a sacculated dilatation of its external cellular coat alone, the internal and middle coats having become ruptured—*mixed aneurism*; or, the blood may become enclosed within condensed cellular texture of the part, external to but adjoining that of the artery, thus forming a sac enclosing blood, and constituting circumscribed *false aneurism*; or, the blood having escaped from the artery into the adjoining cellular texture, may remain diffused therein, constituting *diffused false aneurism*. Whether this condition shall remain, or form a *circumscribed false aneurism*, will depend chiefly on the degree of looseness or density of the surrounding cellular texture, on the size of the artery, and the direction of the opening in it; and, moreover, is regulated by the force and rapidity of the current of blood passing through the vessel. The accompanying figure represents a diffused aneurism becoming circumscribed. (Fig. 53.)

Other forms of Aneurism are recognised by Surgical Authors. *Fusiform* or *Tubular Aneurism*, is a dilatation of all the coats of an artery, extending throughout the entire cir-

FIG. 52.

FIG. 53.

cumference of the vessel, and not forming a sac. It commonly occurs in the arch of the aorta. *Dissecting* aneurism, is sacculated, but the sac is formed between the coats of the artery, and generally between the internal and middle coats, which have become separated or dissected up by the force of the blood, the inner coat having given way. The sac thus situated may extend a considerable distance along the vessel. This condition was first described by Shekelton.

**SIGNS.**—The physical signs of aneurism vary with its condition. *True* aneurism at first presents a small, soft, circumscribed tumour, pulsating, to the touch, to the eye, and to the ear,—as a rasping or sawing sound or bruit,—in unison with each beat of the heart. The pulsation ceases and the tumour itself subsides, if the current of blood through the aneurismal sac be arrested by compressing the artery above the aneurism. And, at this early period, the sac can be emptied by pressure, and the blood thus returned into the artery.

*Mixed*, and *circumscribed false* aneurism, respectively, are not characterized by any peculiar signs; either of these forms of aneurism presenting a circumscribed tumour, and in its early stage, beating and thrilling under the finger, yet being also reducible.

Seeing then that the signs of these three forms of aneurism are indistinguishable, their distinctive names are *practically* useless. In the course of time, the aneurismal sac, enlarging and borrowing more and more fibrine from the passing stream of blood, becomes partially consolidated. The tumour, as felt externally, is, therefore, no longer soft, although still circumscribed; its pulsations are fainter and less expansive, and the swelling cannot be reduced by compressing the vessel above, nor by direct pressure without such force as would break up the clot. The sound or *bruit* also, produced by the pulse-wave of blood through the aneurism, may now be absent; as when the neck of the sac is too narrow to readily admit the current of blood into the sac, or if the sac be consolidated with coagulum. Hence, the characteristic signs of aneurism are modified or absent.

*Diffused* false aneurism, in virtue of its essentially distinctive condition from that of any circumscribed aneurism, might be designated simply,—Diffused Aneurism. The tumour is generally of much larger size than a circumscribed aneurism; its outline is no longer defined, the pulsations are fainter and more indistinct or quite imperceptible; and the blood, being infiltrated, cannot be returned into the aneurismal artery. The swelling resembles a large ecchymosis, the superjacent integuments being discoloured like an extensive bruise. The limb or part dependent on the artery for a due supply of arterial blood, becomes cold and œdematous, threatening gangrene. If the diffused form be *consequent* on circumscribed aneurism, the individual felt something give way suddenly, followed immediately by notable enlargement of the aneurismal swelling; accompanied with intense pain and faintness. The former symptom is due to pressure from the diffusion of blood among the textures and possibly under unyielding fasciæ: the latter symptom arises partly from shock, by the pain thus caused, and partly from the loss of blood in circulation, by its effusion.

The *functional* symptoms of aneurism, are, pain, loss of muscular power, and venous congestion. These do not occur until a rather late period of aneurism, and do not accompany it throughout its career. They, therefore, are neither primary nor constant manifestations, and are inapplicable in aid of an early and exact diagnosis. [P. p. 173].

**DIAGNOSIS.**—The *physical* signs of aneurism, already described, may themselves be absent; as when consolidation in the sac has taken place. Or, if these signs be *present*, they may arise from other causes, other *pulsating* tumours. Such are, vascular or erectile tumours, and certain tumours of a highly vascular character, as encephaloid cancer. The diagnosis will be determined by comparing the signs of these Tumours with those of Aneurism. Then again, a tumour or an abscess seated on an artery, pulsates, and thus simulates aneurism. But, the pulsation of any superimposed mass is not expansive and uniform over its whole surface; the tumour does not subside if pressure be made on the artery above, although the pulsation ceases; and it cannot be emptied by direct pressure. It should, however, be remembered that these negative signs are equally true of aneurism which has undergone consolidation. In some doubtful cases, the tumour can be lifted off the artery; thus plainly declaring its independence. There are also frequently present the characteristic signs of the particular kind of tumour or swelling.

*Diffused* aneurism is far less likely to be equivocal, its signs being more peculiar.

The *history* of aneurism will further aid in determining its diagnosis. If the tumour be circumscribed, by conversion from diffused aneurism; there will be the antecedent transition changes from *that* condition. If diffused, by conversion from circumscribed aneurism, there will be antecedent transition changes from *that* condition; if originally diffused, there will be the antecedent fact of traumatic origin.

**CAUSES, AND EFFECTS OF ANEURISM.**—Aneurism commonly arises from an *internal* cause; namely, a diseased or atheromatous condition of the artery, by fatty degeneration—oil-particles, with crystals of cholesterine (Fig. 54), and subsequently calcareous degeneration; affecting the middle

FIG. 54.

FIG. 55.\*

or muscular coat of the vessel (Fig. 55). In the fatty or atheromatous stage of degeneration the inner aspect of the artery presents slightly elevated patches, yellowish and opaque—underneath the thin inner membranous coat; then, in the calcareous stage, it becomes inelastic and brittle, and the patches assume the character of bony plates—consisting of mineral salts—the phosphate and carbonate of lime, but having little or no osseous structure; lastly, the inner coat or lining membrane gives way, or disappears. The degenerate portion of artery

\* Fatty degeneration of cerebral arteries; a, ultimate capillary; b, larger vessel; c, small artery. (Wedl.)

having lost its elasticity, and perhaps being partially ruptured, is disposed to yield to the pulsating action of the arterial wave-current, and expand into an aneurismal sac. Hence, the formation of *idiopathic* Aneurism, which is primarily circumscribed, and secondarily only becomes diffused, by rupture; or eventually perhaps again circumscribed, by fibrinous consolidation.

The *number* of aneurisms which are liable to form, simultaneously or successively, in the same individual, is mainly determined by the nature of the internal cause in operation. Fatty and calcareous degeneration not unfrequently affects a large extent of an artery, as the aorta, or many arteries, as both popliteals and other vessels. Thence the production of more than one, and even numerous aneurisms in the same person. Sixty-three, for example, were found in one individual, whose body was examined by Pelletan.

*Predisposing* Causes, vary in their nature and degree of influence. *Age* is important, but apparently only as connected with those degenerative changes which the arteries, in common with many other textures, undergo as life advances. Thus, aneurism is most common about the middle period of life, or between the ages of thirty and forty, and subsequently. Certain *blood-diseases* seem to have some predisposing influence. Syphilis, gout and rheumatism, have this reputation. *Climate* appears to possess an inexplicable predisposition; aneurism being far more common in cold than in hot countries. The immunity of the East Indies contrasts favourably with the climate of Great Britain and Ireland. *Occupation* has an unquestionably important influence, and especially in connexion with previous habits of life. Thus, any violent exertion, and by persons who are habitually sedentary, is conducive to aneurism. Hunting, pedestrianism, and other athletic sports, may therefore have this tendency. Such pursuits seem to favour the production of aneurism, by repeatedly exciting a powerful action of the heart and compression of the arteries, in muscular exertion. *Sex* is thus associated with predisposing causes; aneurism occurring more frequently in men than women, in about the proportion of 7 to 1. But, the influence of this and other sources of predisposition, is very variable, and undetermined with regard to their causative importance.

The *external* causes of aneurism are injuries of various kinds affecting the arteries; as, an external wound, a fracture or dislocation, opening an artery; or, a strain, or bruise, inducing sloughing of the vessel. Hence the formation of *traumatic* Aneurism; which is primarily diffused, and secondarily only becomes circumscribed, in favourable cases.

It appears then, that Aneurism arising idiopathically or traumatically, may, respectively, be found either circumscribed or diffused; and conversely, Aneurism, in either of these structural conditions, may, respectively, have arisen idiopathically or traumatically.

These relations of origin and structural condition, in respect to Aneurism, are clearly represented in the following Table:—

#### ANEURISM.

Origin.	{	Idiopathic	{	Circumscribed—primarily.
			{	Diffused—secondarily.
	{	Traumatic	{	Diffused—primarily.
			{	Circumscribed—secondarily.

The *mode* of origin in no way affects the signs and the diagnosis of

Aneurism, here the structural conditions, circumscribed and diffused, are the grounds of distinction ; but the etiology of Aneurism affords the most significant indications as to treatment. This will appear presently. While, therefore, I recognise the perceptible distinctions, circumscribed and diffused Aneurism, I would supplement this diagnosis, by associating therewith that condition of the artery, whether of disease or injury, which is suggested by the origin of the aneurism, as idiopathic or traumatic.

The *effects* of Aneurism, as an internal cause, are both local and constitutional.

*Locally ; circumscribed* Aneurism produces pressure-effects. The sac of blood, fluid or semi-solid, pulsating and gradually enlarging, exerts a constant, expansive and increasing circumferential pressure ; producing various functional disturbances and alterations of structure in surrounding parts, as exhibited by the pressure-effects of popliteal aneurism (Fig. 56). The current of blood, through the artery, being more and more obstructed, or altogether intercepted, the veins are turgid, and œdema supervenes. The nerves become flattened into ribands, occasioning intense pain, or eventually, partial paralysis ; the muscles waste, and the bones erode, without, however, the accompanying formation of pus, as in caries. The bursting of circumscribed aneurism and its conversion into the diffused condition, takes place in two ways. By *sloughing* and rupture of the skin, or of the mucous membrane in certain internal aneurisms ; or, by *fissure* of a serous membrane, if the aneurism burst into the peritonæum, the pleura, or pericardium. The hæmorrhage externally or internally, may be, either sudden and fatal, or recur again and again, and thus at length prove fatal. With *diffused* Aneurism, the functional disturbances—consequent on the circumscribed condition—may persist, or be relieved, temporarily or permanently. Yet with progressive enlargement of the diffused tumour, other, and analogous functional disturbances and structural alteration of surrounding parts supervene. *Constitutionally ;* the operation of Aneurism varies with its structural condition. If circumscribed, the tumour may induce some degree of inflammatory or sympathetic fever, arising from the local irritation ; but this is succeeded by exhaustion, from prolonged pain and sleeplessness. If the aneurism be diffused, the same constitutional disturbances ensue ; and, when circumscribed aneurism becomes diffused, this alteration of structural condition is accompanied, as already stated, by more or less shock, which is due both to the sudden and severe pain, and to the equally sudden hæmorrhage or loss of blood in circulation.

*COURSE, AND TERMINATIONS.*—Aneurism may undergo reparation, or spontaneous cure as it is termed ; or burst, and eventually prove fatal by hæmorrhage, externally, internally, or in both directions.

(1) *Spontaneous cure.*—*Circumscribed* Aneurism is naturally disposed to undergo spontaneous cure. The *essential* nature of this process is coagulation of the blood within the aneurismal sac ; for although coagulation therein may occur naturally under four or five different contingent conditions, as *modes* of cure ; they alike tend to thus obliterate the

FIG. 56.

aneurism. The *principle* of cure will be readily understood. Aneurism arises whenever the force and velocity—the *impetus* of the blood's motion through any given artery—is no longer counterbalanced by the elasticity and contractile force—the resisting strength of the walls of that vessel. Coagulation of the blood within the aneurismal sac tends to restore this resisting strength, and is therefore proportionately conducive to the cure of aneurism. The *details* of this process, and the external *signs* of its progress, are briefly these:—The blood continuing to flow through the aneurism, leaves upon the interior of the sac a thin layer of coagulum, upon which another is superimposed, and so on, forming a lamellated coagulum—the outermost portion of which, attached to the sac, acquires considerable firmness and resisting strength. This consists of distinctly laminated fibrine. (See Fig. 52). It eventually becomes somewhat friable, and resembles boiled beef in colour. The portion of coagulum next in order has the consistence and appearance of damson-cheese; while the innermost portion—in contact with the flowing blood—is semi-fluid, like currant jelly. By this successive deposition of coagulum the sac is gradually filled up to the level of the artery; which still remaining pervious, the surface of coagulum exposed to the current of blood acquires a smooth and membranous appearance. In a large artery, through which the blood flows with most force, coagulation within the *sac alone* may be the whole extent of spontaneous cure. Its external signs are:—gradual solidification of the aneurism; less and less forcible expansion; the pulsation is that of a solid tumour; and lastly, the swelling cannot be reduced by pressure applied to the artery above, or by compressing the aneurism. In aneurism of an artery of the second or third magnitude, through which the current of blood flows less forcibly, coagulation advances from the sac into the *vessel*, which gradually becomes plugged up, above and below, with a coagulum, extending to the next important branch above and below the aneurism. This advance of coagulation is accompanied with the cessation of pulsation. Eventually the aneurism contracts and dwindles into a comparatively small solid swelling; while the artery, to some extent, above and below it, is converted into an impervious fibrous cord. During this process of obliteration, compensation has been gradually made for the loss of the original supply of blood through the artery. The collateral branches above the unobliterated portion of artery enlarge with the additional flow of blood through them, and becoming equal to their extra duty, at length convey as much, or even more, blood than the aneurismal artery formerly supplied. The circulation is adequately restored, and nutrition efficiently sustained, by this compensatory supply of blood.

Remembering the internal cause of aneurism, as already explained, and also the physiological fact that the coagulation of blood is favoured by *rest*, we at once perceive how anything which *retards* the flow of blood through an aneurismal sac tends to restore its resisting strength, and is therefore proportionately conducive to the cure of aneurism. The same effect is produced by anything which *otherwise* favours coagulation of the blood within the sac.

Firstly. The flow of blood may be retarded by a less forcible propulsive power of the heart; in which case coagulation is possibly induced without any co-operative condition incidental to the aneurism itself. The sac is gradually filled up to its brim; then, possibly, the artery is plugged, and finally obliterated. This is the usual mode of spontaneous cure.

Secondly. The flow of blood through an aneurismal sac may be retarded by a piece of clot dislodged from the sac, and washed into the mouth of the distal portion of artery, or impacted within it some distance off.

Thirdly. A piece of clot may be floated down to the aneurism from one higher up, or the retarded flow of blood above may induce coagulation in the lower sac.

Fourthly. The flow of blood may be retarded by the aneurism overlapping and compressing the portion of artery immediately above or below itself.

Fifthly. Coagulation of the blood within an aneurismal sac may be induced otherwise than by any occasion of a retarded flow of blood. Adhesive inflammation possibly, and certainly sloughing, obliterates the sac, and leaves the artery impervious.

Several remarkable instances of spontaneous cure by closure of the sac *alone* are recorded in Mr. Hodgson's work.\* Not only aneurisms of the aorta (p. 119 *et seq.*), but also those of smaller arteries—*e.g.* the brachial and anterior cerebral (p. 130 *et seq.*), were thus effectually closed, without any obliteration of the aneurismal artery. For similar instances, where the aneurisms were due to unskillful blood-letting, the reader is referred to the works of Scarpa,† Petit,‡ Foubert,§ and Saviard.||

In an aneurismal dilatation of the *whole circumference* of an artery—*Fusiform or Tubular Aneurism*—the cure by coagulation is just possible, only modified in a remarkable manner to meet the exigencies of the case. In one case, recorded by Sir A. Cooper, the femoral artery, from its origin to the extent of more than three inches, was dilated into a sac, which was lined throughout with very firm layers of coagulum, having a fleshy appearance. But this deposition did not completely obstruct the passage through the sac; for an irregular canal, in some places larger than the natural bore of the artery, still remained through its centre. The coagulum that formed the immediate boundary of this canal was more condensed than any other portion of the whole, and had a membranous appearance. Here, then, while coagulation had effectually *strengthened* this important artery, its *continuity* was preserved by an adequate channel through the coagulum. Only so much, and no more, coagulum had formed as was absolutely necessary to accomplish this twofold purpose.

Aneurism sometimes terminates safely in another way; but, not implying the favourable course and tendency of this disease, it must be regarded rather as an accidental mode of recovery, by an *evil* occurrence, than as a mode of natural cure, although no assistance is given by art. I allude to the bursting of an aneurism under a tight fascia, or other resisting structure; and compression of the sac and artery, even to obliteration, by the extravasated blood. One example of this kind is related by Sir A. Cooper. An aneurism of the femoral artery, just below Poupart's ligament, having burst, the thigh became enormously swollen. For three days afterwards, pulsation was perceptible over the aneurism. Then, however, it ceased, and the size of the limb began to diminish. At the end of four months, the aneurismal swelling had considerably subsided; the patient could use his limb, and in less than six months he quitted the hospital. Subsequently he died from the rupture

† Treatise on Aneurism, trans. Wishart, p. 351.

‡ Mém. de l'Acad. Roy. des Sciences de Paris, an. 1735.

§ Mém. de l'Acad. Roy. de Chirurgie, t. ii. p. 535. || Journ. des Sçavans, an. 1691.

of an abdominal aneurism, and *post-mortem* examination showed that the femoral artery was obliterated by the pressure of the large quantity of blood effused.

Another mode of accidental recovery through a circumstance itself morbid, is by the pressure of an aneurism of a neighbouring artery, or by that of a tumour not aneurismal. Liston mentions the instance of a subclavian aneurism, which on dissection was found solidified by the compression of another aneurism springing from the innominate artery.

(2) *Diffused Aneurism*, when it remains in this condition, runs the course already indicated by its operation as an internal cause of local and constitutional disturbances. The tumour progressively enlarging even to an enormous size; and ultimately bursting, externally, internally, or in both directions; the career of such aneurism tends inevitably to further and fatal hæmorrhage.

*Duration of Aneurism.*—This would seem to be regulated chiefly; by the force of the circulation, the proximity of the aneurism to the heart, the size of the neck of the sac, and its direction relatively to the current of blood, and by the coagulating power of the blood. Rest, and the mode of treatment, will further affect the duration of aneurism. But the course of all aneurisms is generally slow; extending to a few months, a year, or possibly several years. The slow dilatation of aneurism was established by a series of cases which John Bell collated with his usual care; and in one extreme case of femoral aneurism recorded by Hodgson, the period of its duration was twenty years.

*PROGNOSIS.*—The prognosis of Aneurism should be determined mainly, by a due consideration of the persistency, or otherwise, of its causes. [P. p. 716]. Degeneration of structure affecting the coats of an artery, implies the loss of that adequate resistance and resiliency to the current of blood, which having given rise to Aneurism will also perpetuate it. The extent to which degeneration usually affects the arterial system, more than one artery being the seat of this destructive change, is an additionally unfavourable consideration. Hence, a *single idiopathic* aneurism always suggests a suspicious prognosis. *Traumatic Aneurism* suggests an unfavourable prognosis, only in proportion as the aneurismal swelling is progressive. The conditions which mainly regulate the *duration* of aneurism are obviously important, as persistent causes in regulating its dilatation and progress. In so far as these conditions are discoverable during life, their consideration will complete the prognosis.

*TREATMENT.*—Remedial measures—hygienic, medicinal, and operative—should be entirely responsive to the natural or spontaneous cure of aneurism. The ordinary mode in which natural cure takes place, is, by retardation of the current of blood through the aneurismal artery, sufficiently to induce coagulation and the deposition of laminated fibrine within the sac.

i. As conducive to this end, the primary indication of treatment is *rest*, prolonged rest, of mind and body. *Position* is an important adjunct, by taking off the force of the arterial current. The recumbent position will be most suitable for aneurism in any part of the body. *Gradual starvation* and *depletion*, to diminish the quantity of blood in circulation, and to reduce the force of the heart's action, have some remedial influence; but only within judicious limitations. Farinaceous, rather than animal food, a sparing proportion of liquids, and total abstinence if possible, from stimulants; constitute the chief features of the diet to be

observed. That which was recommended by Bellingham, answers to this description. It consisted of two ounces of bread-and-butter for breakfast, two ounces of bread and the same quantity of meat for dinner, and two ounces of bread for supper, with a little milk and water, occasionally, sipped in small quantities. Depletion, by watery purgatives, is preferable to blood-letting; and should the latter be resorted to, it is, in Sir Thomas Watson's judgment, remedial only so far as it reduces any excessive force of the circulation. The small and repeated bleedings practised by Valsalva, may be advantageous, in some cases; but certainly not when pushed to the extreme he advocated; syncope, when the patient attempted to stand, or even on rising in bed. Respecting *medicinal* measures for controlling the heart's action, I have no authentic information to offer. The therapeutical results of medicines having reputed efficacy in relation to aneurism, are vague and unsatisfactory.

Having succeeded in lessening the *force* of the circulation, sufficiently to diminish the expansive pulsation of the aneurism; are there any known means of *directly* favouring the *coagulation* of blood, and the deposition of laminated fibrine, within the sac? By increasing the quantity of fibrine in the blood and its tendency to coagulate, in short, by improving the plasticity of the blood itself, this indication may be fulfilled. Animal food, therefore, should now be substituted for farinaceous, and in larger quantity: but the same restriction, or nearly so, should be observed with regard to liquids, and particularly stimulants. This combination of treatment, for lessening the force of the general circulation, and then supplying the fibrinous material for coagulation; constitute the régime originally proposed by Valsalva. Pathologically correct in itself, it was wrong only in the extreme degree to which he carried it practically.

Certain *local* applications externally are said to aid the coagulation of blood within the sac, but their efficacy is doubtful. Ice enjoys the repute of being thus beneficial; its constant or repeated application, is, however, apt to endanger sloughing of the integuments. Its occasional use may relieve pain. But, for this purpose, the belladonna plaster, or an embrocation composed of equal parts of oil and of the strong tincture of aconite; form topical appliances which, according to Mr. Erichsen's experience, afford much relief.

ii. *Mechanical, and Operative, resources*; obediently to the *first* mode of natural cure.

In the event of an endeavour to reduce the force of the *general* circulation, and thus to favour coagulation in the sac, having proved unsuccessful; recourse must be had, without further delay, to such local measures as may retard the force of the arterial current through the *aneurismal artery*, exclusively. Mechanical appliances for this purpose, favourably contrast with any cutting operation. The former mode of treatment anticipates the necessity for obliterating the aneurismal artery, and avoids also the danger consequent on any operative procedure for securing the vessel.

(1) *Compression* of the artery *above* the aneurism. This plan of mechanical treatment should be guided by two principles. It is unnecessary to entirely arrest the stream of blood through the artery above the aneurism, and therefore unnecessary to obliterate the vessel by inflammation, in order to effect a cure. It is only requisite to lessen the *force* of the stream, and *temporarily*; thus to give a fair start to the deposition of laminated fibrine, and so at length regain the balance of resistance naturally offered by the artery to the pulse-wave of blood passing through it. A

degree of compression just sufficient for this purpose, and applied intermittently for a few hours daily, will represent the kind and amount of assistance necessary; instead of complete occlusion and by continuous pressure, which might lead to obliteration of the artery. This, the old method of compression, as employed by Dubois and Pelletan, has been judiciously superseded by the more conservative modification introduced by the Dublin school, and with which the names of Bellingham, Hutton, Tufnell, and Carte, are principally associated. Compression is the means employed, in either case; but the old method was simply blind empiricism, the modern one, is a strict imitation of the mode of natural cure.

*Instrumental Compression.*—Various forms of Instruments have been devised for compressing an artery, above the seat of aneurism. The *compressor* used may be in the shape of the horse-shoe or Signoroni's tourniquet (Fig. 57); or that invented by Carte, the advantage of which is, that it provides an elastic and yielding pressure, instead of the unyielding force of the screw.

FIG. 57.

Before applying this or any compressor, the limb should be evenly bandaged, to prevent congestion of the vessels, as much as possible; and the irritation occasioned by the pad of the instrument, may be much prevented, by shaving and powdering the integuments of the part. The degree of compressing force appropriate should be estimated by its effect in controlling the pulsations in the aneurism; it being only necessary to suspend them, without entirely arresting the transmission of blood. The total duration of intermit-

tent compression requisite, may be estimated by its effect in promoting coagulation and consolidation of the tumour; the period necessary for this purpose varying considerably, from a few days to some months. Thus, in 26 successful cases,\* this period ranged between sixty hours and eight months; its average duration being nineteen days.

No medicinal treatment is indispensable to the completion of the process of cure, when thus aided by compression. If, notwithstanding the precaution of shaving and powdering the part, pain be occasioned by the pad in such degree as to disturb sleep, then indeed opiates may be administered; but, in most cases, this inconvenience will be anticipated by proper management of the instrument. It is well to try it on, so to speak, gently at first, and augment the pressure by little instalments; also to shift the pad from place to place in the course of the artery; and, as Tufnell suggested, to lighten it slightly, so that when the patient has fallen asleep, the pressure may be renewed without awakening him. This plan of treatment being a faithful imitation of the process of natural

\* Medical Times and Gazette. Statistical Results, by J. Hutchinson.

cure by retardation of the passage of blood through the aneurism ; it is not surprising to find that the anatomical condition induced is the same as that resulting from the unaided process. In both cases, the aneurism is solidified and partly absorbed, leaving the artery pervious ; while collateral branches proceeding from the parent trunk, are enlarged ; thereby contributing to maintain the circulation and nourishment of the limb below the seat of aneurism. Thus, during compression of the femoral artery, for popliteal aneurism, three arteries are observed to undergo enlargement ; one passing over the centre of the tumour, another externally, over the head of the fibula, and a third internally, along the inner margin of the patella. This observation, originally due to Tufnell, is corroborated by Mr. Erichsen.

The *statistical* results which appear most worthy of credit, with respect to compression as practised in England, are those collated by Mr. Hutchinson from the Metropolitan and Provincial Hospitals. Of 70 cases, 46 were popliteal aneurism, and in 24 of them, this treatment was successful. The remaining 22 cases had reference to the treatment by ligature of the femoral artery, as compared with compression. The experience of the Dublin Schools is far more favourable. Of 25 cases collated by Bellingham,\* in 1 only was the ligature subsequently resorted to.

The only disqualification of instrumental compression for the treatment of aneurism, is its *impracticability* in certain parts of the body. It is almost necessarily restricted to the treatment of femoral and popliteal aneurisms.

*Direct* compression of the aneurism was formerly practised, with the view of opposing the *expansive* force of the current of blood and consequent enlargement of the sac. But pressure thus applied, not being designed to check the force of the current *through* the aneurismal portion of artery, was an unpathological mode of treatment ; and moreover, it was apt to cause inflammation and sloughing of the sac. This modification, therefore, which was first employed by Bourdelot, and adopted by Guittani, Heister, and other Surgeons, not unsuccessfully, at length gave way to compression on the cardiac side of the artery.

*Digital* compression, or pressure with the fingers, may be conveniently applied to aneurisms, in situations ineligible for instrumental compression. They are chiefly those of the axillary, subclavian, and carotid arteries. In these situations, pressure with the fingers on the cardiac portion of the aneurismal artery, will aid the natural process of cure by retarding the flow of blood through the sac. The requisite continuance of compression is provided for, by having a sufficient number of assistants ; each, in turn, taking charge of the vessel before the previous one withdraws his finger, and observing to apply only that degree of pressure which controls the pulsations in the aneurism. Having maintained compression, in this way, for a few hours, the patient may be advantageously allowed a period of intermission, followed by its reapplication, and so on alternately. The total duration of these periods necessary to complete the cure, varies of course in different cases. In 19 cases successfully treated by digital pressure, the average number of hours was not more than forty-one and a half ; spread, however, over a variable period of time, owing to intermissions of the pressure. Whereas, according to the most favourable reports of those who are greatly interested in the treatment by instru-

\* Observations on Aneurism, and its Treatment by Compression, 1847.

mental compression, the average duration of treatment by that method, was twenty and a quarter days in each case.\*

Digital compression, for the cure of aneurism, is of quite recent date as compared with instrumental compression. In 1846, Professor Vanzetti first attempted it for the cure of a popliteal aneurism, at the Hospital of Karkof, in Russia. The case was deemed unsuccessful after only two days' treatment, and forthwith a ligature was resorted to. The particulars were not published until 1858.† Meanwhile, in 1848, Dr. Knight,‡ of Newhaven, United States, for the first time, successfully employed digital compression, as the sole means of cure; in a case of popliteal aneurism, and which had resisted compression by every kind of instrument. At the end of 48 hours' pressure, thus applied to the femoral artery, the tumour in the ham had become one-third smaller, hard, and pulseless. The treatment was then discontinued, and four months subsequently, the tumour could scarcely be felt. Encouraged by this and similar cases, digital compression has since been on its trial, and this method now bids fair to rival instrumental compression. It is more simple, comparatively painless, a more speedy cure, equally effectual, and as permanently so.

Compression by *flexion*, is another, and even yet more simple method of pressure; but limited in its applicability to aneurism situated in the flexure of a joint. Thus, the cure of popliteal aneurism may be effected, simply by flexing the leg on the thigh and securing it in that position by a bandage, previously rolled round the limb from the toes upwards to prevent congestion. The degree of flexion requisite is an acute angle in the first instance; or better, a right angle only, at first, and gradually diminished. The duration of genuflexion necessary can scarcely yet be averaged. In the first successful case on record, that by Mr. Ernest Hart,§ the cure was considerably advanced after the first day, and complete on the fourth; on the seventh day the patient was moving about. In a case by Mr. Shaw,|| the cure was far more protracted, the cessation of pulsation not having been observed until the 30th day; but in this instance, the tumour was of larger size. Many cases also are reported in

which flexion has been successfully used in combination with pressure. One, by Mr. Pemberton,¶ another by Mr. A. Pritchard.\*\*

(2) *Ligature*.—(a) Ligature of the aneurismal artery on the *cardiac* side, and at *some distance* from the sac—in a *sound* portion of artery. This is the Hunterian operation for Aneurism. (Fig. 58, middle figure.) The application of a ligature to any part of an aneurismal artery, divides the vessel when the ligature separates; thus permanently intercepting the transmission of blood through the artery, itself perhaps a main trunk.

FIG. 58.

\*\* Brit. Med. Journ., 1861, March 30th.

This treatment, therefore, should be an ulterior resource to temporary compression, in any form; obliteration of the vessel not becoming necessary until after temporary compression—preceded by hygienic (and medicinal) measures, for retarding the general circulation—has failed.

Ligature on the cardiac side of an aneurismal artery, as a surgical procedure, is another illustration of treatment in accordance with the mode of natural cure by retardation of the current through the aneurismal artery; but it is a further concession of such assistance, and proportionately less conservative. I have, therefore, postponed the consideration—as in practice, the application—of compression by ligature; until after that of other handy modes, without any surgical operation, have been tried and found wanting. Then; if the heart be competent to withstand the obstruction to the circulation consequent on the operation, and no internal aneurism complicate the case;—under these *favourable* circumstances, obliteration of the aneurismal artery, by ligature, is a justifiable resource.

There are, however, certain *unfavourable*, if not positively contra-indicating, circumstances, with respect to this extreme measure. Ossification of the artery at the seat of ligature, would be a decidedly adverse condition. But this can scarcely be discovered prior to operation. A rapidly enlarging aneurism is unfavourable, as evincing an indisposition to the deposition of laminated fibrine. Then again, a very large aneurism is unpropitious, as threatening gangrene of the limb; an event almost inevitable, if the circulation were suddenly cut off by ligaturing the artery. Inflammation of the sac will be an unfavourable condition, by possibly proceeding to suppuration; and suppuration itself would be a positively forbidding condition, by rendering the result of ligature abortive.

The Hunterian operation, first performed in December 1785, consists in applying a ligature, on the cardiac side of the aneurism, to a *sound* portion of the artery; and therefore at some distance above the aneurism. For popliteal aneurism, the superficial femoral artery is ligatured, where this vessel is crossed by the sartorius muscle, in the middle third of the thigh. The force of the current of blood having been thus reduced, coagulation within the sac is promoted, yet without cutting off the supply of blood entirely. A sufficient quantity is transmitted for the process of coagulation, by collateral branches issuing from the artery above the ligature and communicating with the vessel below, but above the aneurismal sac; while there is also a sufficient quantity of blood transmitted onwards, and also by collateral branches which become adequately enlarged, for the maintenance of the limb below. (Fig. 59.) Meanwhile, coagulation and the deposition of laminated fibrine is proceeding in the aneurismal sac, and it extends into the artery as high, perhaps, as the ligature; both the sac and this portion of the artery thus become consolidated; the ligature separates, in the usual manner, by sloughing of the ring of artery within the noose, and the divided

FIG. 59.

ends of the vessel are simultaneously sealed with plastic lymph. This takes place in a period ranging from ten days to a month; but varying chiefly according to the size of the artery, and the plastic power of the individual. Of fifty-four cases recorded by Crisp, in which the femoral artery was ligatured, the average period for the separation of the ligature was eighteen days. Finally, the consolidated aneurism and artery undergo partial absorption; so that the latter withers and degenerates into a fibrous cord. The limb, nourished by the collateral circulation, may nevertheless become somewhat atrophied.

(b) Anel's operation, 1710, contrasts with the Hunterian, in its ultimate *purpose*, more than as an operative procedure.

The operation proposed by Anel, was to ligature the aneurismal artery, on the cardiac side, but *close* to the aneurism. (See Fig. 58, left figure.) The aneurismal blood escaping through the distal portion of artery, the sac would, it was thought, collapse, and thus the tumour disappear. For this purpose, the blood must remain fluid in the aneurism, instead of undergoing coagulation and the deposition of laminated fibrine, with occlusion of the sac, followed by the absorption of both, the tumour disappearing in that way. Although, then, these two operations are somewhat similar, they differ widely in their ultimate purpose as to their modes of cure. Moreover, Anel, having performed his operation once only, and for *traumatic* aneurism of the brachial artery at the head of the elbow, he never himself repeated it, nor advocated its repetition, in similar cases. He apparently regarded his operation as applicable only in that particular case; unlike Hunter, as a *conception* ruling the treatment of a large class of cases.

It is with reference to *idiopathic* aneurism—as implying a diseased state of the artery—that the operations of Anel and Hunter notably contrast; and when compared with the only operation which had previously been designed for the cure of such aneurism.

The *old* operation, or that of Antyllus, consisted in extirpating the aneurism. An incision was made throughout the whole extent of the aneurismal sac, in order to scoop out the coagulum and expose the two orifices of the artery leading into the sac; immediately above and below those points a ligature was passed round the vessel, securing it in both directions. But an *unsound* portion of artery was thus selected—that immediately above and below the sac, which participated in the degenerative change of structure that originally gave rise to the aneurism. Hence, secondary hæmorrhage, perilous or perhaps fatal, generally occurred when either ligature separated, and as often necessitated amputation; while invariably, the large wound of the aneurismal operation healed tediously and often precariously to life by exhausting suppurative discharge. In Hunter's operation, a *sound* portion of artery was selected, thus avoiding these evil consequences. This operation, therefore, at once superseded that of Antyllus, and Anel's also—the ligature having been applied equally close to the aneurism in that operation. But the principle of Hunter's operation—in relation to the *natural cure* of aneurism, differed even more essentially from both these operations; in the assumption that it was necessary only to reduce the force of the circulation by applying the ligature at some distance from the aneurism, for the process of natural cure to supervene, instead of entirely arresting the current of blood through the aneurism by ligaturing the adjoining portion of artery.

*Signs after Ligature, by Hunter's Operation.*—Certain alterations in the

signs of aneurism, attend or follow the Hunterian operation of ligature. The aneurism ceases to pulsate and partially subsides. These changes taking place immediately the ligature is drawn tight, are valuable signs of its successful application. The circulation of blood being proportionately arrested in the limb, it becomes numb and cold, and its muscular power is diminished. As the collateral circulation is established, these immediate effects disappear, and the temperature of the limb may rise above that of its fellow.

*After-treatment.*—The treatment *after* this operation should be directed to avert the temporary tendency to gangrene, pending the establishment of an adequate collateral circulation. Hence, the circulation and temperature of the limb must be maintained. A thick wrapper of carded wool answers most effectually, aided by a suitable elevation of the limb to relieve congestion. A moderately nourishing diet with stimulants, and the judicious administration of opium, will tend to sustain the process of cure.

*Consequences.*—Certain *unfavourable consequences* and *evil results* may ensue from this application of the ligature for aneurism.

1. *Pulsation may continue or return* in the aneurismal sac. The small stream of blood conveyed by collateral branches into the artery below the ligature, and thence into the sac, depositing the laminated fibrine, is not a pulsatory current. If, however, these feeding vessels are larger than sufficient for this purpose, pulsation continues, or soon returns; if they enlarge immoderately, then also pulsation returns. Any regurgitation of blood into the sac, from below, and therefore in opposition to the current, need scarcely be taken into account. If it occur, it will cause gradual enlargement of the aneurism, without pulsation; simulating the gradual increase of a malignant tumour. Rarer causes are these—Any condition of the blood, which, delaying or hindering coagulation, disposes it to remain fluid in the sac, will favour the continuance of pulsation. A vas aberrans may exist, which communicating directly, or indirectly, with the aneurism, thus continues its pulsation. An instance of this kind occurred to Sir Charles Bell.\* He ligatured the femoral artery for popliteal aneurism. The patient died a week afterwards from erysipelas; and it was then discovered that the femoral artery was double, and that the vas aberrans had continued to supply blood to the aneurism in the ham, after the operation. Yet in this case, the sac had become completely consolidated with coagulum, and in the short period of one week. The preparation is in the museum of University College, London. Other contingencies—by which the pulsation of an aneurism continues after the application of a ligature—relate to the operation. The ligature may not have been applied to the aneurismal artery; or having been applied thereto, the noose may have been tied obliquely, instead of transversely, then shifting its place and loosening its hold, the pulsation continues, or returns, soon after the operation.

Of all these causes of pulsation after the Hunterian Operation for aneurism, that arising from an undue collateral circulation, as explained, is by far the most common. But it occurs with different degrees of frequency in different arteries. In carotid aneurisms it is most frequent. Of 31 cases, in which the carotid artery was ligatured for aneurism, pulsation continued or returned in 9; whereas of 92 cases of inguinal aneurism, in which the external iliac artery was ligatured, pulsation

\* London Medical and Physical Journ., vol. lvi. p. 134.

returned in 6 cases only. In axillary and popliteal aneurisms, respectively, recurrence of pulsation is an exceptional event.

It should be remembered that a slight thrill may very frequently be felt in an aneurism, on the second or third day, after the application of a ligature by the Hunterian method. This, however, is a favourable occurrence, as it bespeaks a feeding stream of blood for coagulation in the sac; and it supervenes with about equal frequency in all aneurisms, irrespective of any particular portions of the arterial system, and the distribution of vessels accordingly. The thrill, thus arising, soon subsides—with consolidation of the sac. Returning pulsation, on the other hand, if it occurs, usually begins at a much later period, not until a month or six weeks have elapsed, and continues for some time.

Returning pulsation is seldom persistent, and rarely terminates fatally. Of 26 cases in which pulsation returned, 3 only were fatal, and then not owing to this event, but by sloughing of the sac.

2. *Secondary Aneurism*, or aneurism reappearing by *redilatation* of an aneurismal sac, which had previously undergone consolidation and absorption, is an extremely rare event. This must not be confounded with returning pulsation. Mr. Erichsen believes there are only two unequivocal instances on record, both of which were in the ham; the original tumour having disappeared entirely, this secondary disease made its appearance, after the lapse of six months, in one case; and after four years, in the other instance. Secondary Aneurism, in the sense of another *distinct* aneurism arising close to the former one, double aneurism, in fact, is quite another matter.

*Treatment of Pulsation; continuous or returning.*—This, of course, must have reference to the cause or causes of the pulsation. Arising, in most instances, from an undue collateral circulation communicating, directly or indirectly, with the sac; the pulsation will cease as the deposition of laminated fibrine proceeds therein. The process of natural cure rights itself. Failing this result; the balance between the deposition of fibrine and the supply of blood, may be slowly gained, or regained by sufficiently elevating the limb; while the pulsation can be directly restrained by moderate pressure on the aneurism, with a compress and roller, evenly applied. These resources not proving effectual, the coagulating power of the blood deserves consideration; but our knowledge respecting its operation within the body is at present very limited. Here then pathology fails to guide the treatment. The presence of a *vas aberrans* is discovered at the time of operation, by ascertaining whether the ligature *entirely* controls the pulsation of the aneurism. If not, the tributary vessel should be sought. It will not be far off, and it must be secured by another ligature. In like manner, the aneurismal artery is *identified*, by trying the pulsations of the sac, when the supposed aneurismal vessel is commanded above; but this should be done *before* the ligature is applied. Lastly, application of the ligature *transversely* round the artery, will avoid any chance of pulsation continuing or returning, as occasioned by shifting of the noose.

Extreme cases, which baffle all these resources and precautions, necessitate further operative proceedings. *Reapplication* of the ligature may have to be resorted to; either lower down the artery—nearer the sac, as an approach to Anel's operation—or, by opening the sac, turning out the clots, and tying the artery immediately above and below—the old operation of Antyllus. I know of no *data* for determining the Surgeon's

choice, but the latter operation, whereby Nature's work of coagulation and consolidation is undone, should be resorted to reluctantly. *Amputation* is the very last resource.

3. *Gangrene of the limb* proceeds from causes of an opposite character to those which induce pulsation in the aneurism, after the Hunterian operation. The latter are conditions which favour an undue collateral circulation through the sac; the conditions to which I now allude retard any collateral circulation. *Firstly*; an aneurism itself retards the current of blood through the artery, and operates also by compressing the neighbouring vessels; thus preventing the transmission of arterial blood, and the return of venous blood. Gangrene threatens. The application of a ligature to the aneurismal artery is an additional obstruction, rendering the condition more perilous; and if the collateral circulation be interrupted by the large size of the aneurism compressing the neighbouring vessels, then gangrene ensues. *Secondly*; surgical mismanagement of the limb, after operation, by inattention to position and temperature, or the presence of any morbid condition which lowers the vitality of the limb, will severally tend to induce gangrene.

It supervenes in a period, varying from the third to the tenth day; but in rare cases, not until the third week. (Porter.)

*Treatment*.—So far as gangrene is due to the ligature, it cannot be prevented; but if due principally to interruption of the collateral circulation by pressure of the sac, this source of obstruction can be removed by the old operation of cutting down upon the sac, laying it freely open, and turning out the clot. At least two such successful cases, both of popliteal aneurism, are on record; one by Lawrence,\* another by Benza. Other preventive measures, topical, dietetic, and medicinal, have already been noticed in reference to the appropriate treatment after ligature. With gangrene, as with recurring pulsation, amputation of the limb is our last resource; and the operation must be performed above the situation of the ligature.

4. *Suppuration and sloughing of the sac*, is attended with the usual symptoms of inflammation—heat, pain, and throbbing. At length the integuments give way, and portions of clot escape, having various degrees of consistence and shades of blood-red colour. Then hæmorrhage of fluid arterial blood occurs, either with a fatal gush, or recurring in small but increasing quantities. Which form of hæmorrhage shall take place is apparently determined by the degree to which consolidation of the aneurism has advanced; and, therefore, in a measure, by the time of its occurrence after ligature. The amount of hæmorrhage is regulated in like manner, it being most free and uninterrupted in the event of pulsation continuing or returning.

The *causes* of suppuration and sloughing of the sac, and of hæmorrhage thence arising, in the course of aneurism, are any conditions unfavourable to the vitality of the sac. Hence, the large and increasing size of an aneurism, and the imperfect coagulating power of the blood therein, have this tendency. So also any external injury to, or irritation of, the sac. Considering these and other similar accidental circumstances, the period after ligature when suppuration may supervene, is, obviously, very uncertain. It may happen at any time in the subsequent course of the aneurism. The average time is, perhaps, between the third and eighth

\* Medical and Physical Journ., vol. lv.

weeks, but in a case of carotid aneurism recorded by Sir A. Cooper, suppuration occurred at the eighth month after operation. Comparatively few cases terminate fatally; probably not more than one in four, and then, generally, by hæmorrhage.

*Treatment.*—This will be guided by the stage and result of suppuration. In the first instance, the sac should be treated as an ordinary abscess; only that when an incision is made, it should be free enough to turn out the whole of the clot. Any remaining portion is likely to putrify and become a fœtid, purulent discharge; but when removed entirely, the sac is in a condition to heal from the bottom by granulation. *Hæmorrhage*, of course, is imminent. A tourniquet, therefore, loosely applied to the limb above, will be a judicious precaution which can be brought into use at any moment. In the event of hæmorrhage; loss of blood may be temporarily stayed by a compress of sponge well placed at the bottom of the sac, over its mouth; and of sufficient size to be secured in position by a roller, evenly applied. Then comes the question of how to permanently arrest the hæmorrhage? The diseased state of the artery immediately above and below the sac, in idiopathic aneurism, forbids the application of a double ligature *in situ*, as by the old operation. Ligature of the artery higher up than was performed prior to suppuration, would probably be the turning point for the commencement of gangrene. In this dilemma, the Surgeon may advantageously wait and see what Nature can accomplish, as the healing process of granulation closes over the arterial aperture in the sac; guarded always by the compress, and during its reapplication occasionally, by tightening the tourniquet.

This faithful following up of Nature's operation having failed, our only resource is amputation.

5. *Secondary hæmorrhage* from the operation-wound, after ligature by the Hunterian method, is an event unconnected with the course of Aneurism. It is a failure of the operation; and, as it arises from sloughing of the included portion of artery before the preparatory closure of either or both ends of the vessel has taken place, the hæmorrhage occurs whenever the ligature separates. The average time was the 18th day, in 54 cases, recorded by Dr. Crisp, of ligature applied to the femoral artery. It is more likely to occur, the nearer the artery is to the heart, the central force of the circulation.

The *treatment* in this case is not presumed to be restricted by any diseased state of the artery, at the seat of ligature. Consequently, the re-application of *two* ligatures, one to each end of the artery at the point of division, will most probably prove effectual; the former operation-wound having been just sufficiently reopened for this purpose. Temporarily, the hæmorrhage may be arrested or checked, by plugging with sponge or lint.

*Statistical Results.*—Ligature for Aneurism shows a considerable mortality. In 256 cases of this operation on the larger arteries, the deaths were about 22 per cent. This was shown by Dr. Crisp's tables. The result of investigations by Porta is even more startling. In 600 cases of ligature for diseases and injuries indiscriminately, the mortality rose to 27 per cent. Then again, as compared with *compression*, the balance is decidedly in favour of the latter mode of treatment. Thus, according to Norris; of 188 cases of ligature for femoral and popliteal aneurisms, 142 were cured, 46 died, 6 limbs were amputated; in 10 suppuration of the sac supervened, and in 2 gangrene of the foot; giving

a total, of deaths, about 1 to 4, and failures 1 to 3. Whereas, of 32 compression cases, also of femoral and popliteal aneurisms, collected by Bellingham; 26 were cured, in 1 ligature was resorted to after compression had failed, in 2 amputation became necessary, in 1 death occurred from erysipelas, in 1 from chest-disease, and in 1 instance, the pressure was discontinued. The failures of compression were, therefore, only as 1 to 5.3; and the deaths only as 1 to 16. Even where compression itself fails, it most advantageously prepares the way for success by ligature. Thus, according to Mr. Hutchinson's Report, in 22 cases of ligature of the femoral artery, previously treated by compression, 2 only died of gangrene; whereas, in only 10 such cases, without preparatory compression, 3 deaths occurred from this cause.

iii. *Manipulative*, and *Operative* resources, obediently, or corresponding, to the *second* mode of natural cure—*i.e.*, retardation of the passage of blood, through the aneurism, by obstruction of the *distal* portion of artery; a piece of clot being dislodged from the sac and washed into the mouth of the distal portion, or becoming impacted within it, some distance off.

(1) *Manipulation*.—This plan of treatment was introduced by Sir W. Fergusson. It consists in so thumbing the aneurism as to dislodge a piece of clot into the distal portion of artery. The manipulative procedure designed for this purpose, is thus described.\* “The patient was seated in a chair, and I placed the flat end of my thumb on the aneurismal tumour so as to cover the prominence. I then pressed, until all the fluid blood had passed from the sac, and I could feel that the upper side of the aneurism was pressed against the lower. I now gave a rubbing motion to the thumb, and felt a friction of surfaces within the flattened mass. The movements were little more than momentary, but they were such as I had preconceived.” Two cases of subclavian aneurism were subjected to this treatment; neither was unequivocally successful, and both were attended with very alarming symptoms at the time of manipulation. In the first case, the aneurism never ceased to pulsate, and after eight months, terminated fatally by rupture of the lower and back part of the sac. The axillary artery was found to be firmly plugged with fibrine. In the second case also, the aneurism continued, but the pulse ceased at the wrist. At the end of two years, and after hard work as a sailor, the aneurism itself had disappeared. In both cases, giddiness and faintness were immediately produced by the manipulation; and in the second case, these symptoms were succeeded by hemiplegic paralysis of the left side, from which, however, the patient recovered in two months.

So far the results of treatment by manipulation were not very encouraging. More disastrous cases occurred in the hands of Esmarch† and Teale of Leeds.‡ Both were carotid aneurisms. On the other hand, an aneurism of the right subclavian artery, thus treated by Mr. R. Little,§ proved quite successful, although not without the disadvantage of temporary paralysis of the arm. Two successful cases in aneurism of the lower extremity; one of the femoral artery, treated by Dr. G. E. Blackman, of Cincinnati,|| and the other of the popliteal artery, by Mr. Teale,¶

¶ Op. cit.

are, I believe the only additional results, at present, in favour of this method of treatment.

(2) *Compression*, or *Ligature*, of the *distal* portion of an aneurismal artery, represent other methods of imitating the second mode of natural cure; although the obstruction, as thus effected, is not by the impaction of a piece of clot in that portion of the vessel. The operation by ligature of the distal portion, is principally associated with the names of Brasdor and Wardrop (see Fig. 58, right figure). Whether the arterial current be obstructed in this way, or simply, by compression of the artery at that part of its course; in either case, the purpose is, to retard the stream of blood *through* the aneurism, and thence induce the deposition of laminated fibrine with consolidation of the sac.

The immediate effect of distal obstruction, is to turn the full force of the arterial current into the sac; which being distended, may at once yield and burst with fatal hæmorrhage. Should this issue not occur, the collateral branches of artery from the main trunk above the aneurism, will probably have time to enlarge sufficiently to carry on the circulation for the maintenance of the limb; a small feeding stream of blood passing down also to the sac, which undergoes consolidation and obliteration by the process of natural cure. But this happy issue is very precarious and doubtful. According to the results of 27 cases collected by Mr. Erichsen, 20 terminated fatally soon after the operation, and in the other 7 cases, although the patients survived the effects of ligature, the disease remained uncured.

I pass over the *third* and *fourth* modes of natural cure, as they are modified illustrations of either the first or second mode, respectively (p. 326); the fourth mode also illustrating both the first and second. But the conditions by which the curative process is induced in the third and fourth ways are of very rare occurrence in Nature, and have no imitations by Surgical Art.

iv. Certain *Operative* procedures, of a *physical* or *chemical* character, correspond to, if they do not imitate, the *fifth* mode of natural cure; that by inflammation of the sac, and its consequences. *Galvano-puncture* has been practised for the purpose of inducing coagulation of the blood, *en masse*, within the sac. Two needles connected with the wires of a galvanic battery, are introduced into the sac, in opposite directions, until they touch, and fibrine becomes deposited around one of the poles, or needles. The action of the battery should be continued for about ten minutes, and repeated several times.

Under this galvanic influence, a soft clot may form which partially fills the sac; but acting as a nucleus it may induce the deposition of laminated fibrine, and at length occupy the whole sac. Or, a large but loose clot having formed, in the first instance, it may settle down, and thus the sac become consolidated. Or lastly, the current of electricity excites inflammation of the sac, rather than coagulation of its contents; and this may be followed by coagulation, or by suppuration with sloughing of the sac and its obliteration. These are successful issues. But there are cases, and not a few, of an opposite kind. The clot liquifies, pulsation is re-established, and the disease resumes its course. This relapse, after galvano-puncture, is probably due to the mode of coagulation thereby effected; the mass of blood setting suddenly into a semi-solid state, instead of consolidating by the gradual deposition of laminated fibrine. Then again, in the event of inflammation supervening, sloughing is mostly

accompanied with hæmorrhage which may be fatal to the patient's limb or life. Apart from any adverse issue, the pain occasioned by galvano-puncture, is always hard to bear, in some cases intolerable; and the administration of chloroform would be injudicious.

Galvano-puncture is of comparatively recent date. First introduced by Mr. B. Phillips, in the year 1832, it was subsequently followed up by Liston, Gerard, and Keate;\* but with so little success that it fell into disuse. A few years later, however, this proceeding was practised by Pétrequint† and Burci with more success, and thence its revival as an occasional expedient. It is justifiable only, or chiefly, in cases of internal aneurism, or of aneurism at the root of the neck; in fact, where compression, ligature, or any other method of treatment, has failed, or is impracticable.

The *statistical results*, hitherto recorded are very unfavourable. According to Bonnet, up to July, 1851, 23 cases of aneurism had been subjected to this treatment; 8 were of the brachial artery, 7 of the popliteal, 2 of the subclavian; 1 of each of the following arteries — ophthalmic, temporal, carotid, thoracic-aorta, ulnar; and 1 unknown. Of these, 13 cases were unsuccessful, and although 9 were reported as successful, 7 of them were due rather to compression and the application of ice, or to inflammation and suppuration of the sac, than to galvano-puncture. It failed, therefore, in no less than 20 cases out of 23; leaving only 2 favourable results, excluding the unknown case. Subsequently, out of 50 cases, collected by Ciniselli,‡ 23 were cured, 20 were not cured, and 7 were fatal.

The *injection of coagulating agents*, has been practised, like galvano-puncture, with the view of inducing coagulation *en masse*, within the sac. Various such agents have been tried. The least hazardous, and the most efficacious, appears to be, a weak solution of perchloride of iron, used in small quantity. A solution of 20° Beaumé, is the highest degree of strength recommended by Vallette; and twenty drops only to every 100th of a pint of the blood in the sac, is the quantity permitted by Broca. The safest instrument for injecting is a small glass syringe, graduated, furnished with a screw piston, and a fine-pointed nozzle. (Fig 60.) Before introducing it, the circulation through the artery should be suspended by compressing the vessel carefully on either side of the aneurism. Then the point should be thrust perpendicularly into the aneurism, until a drop or two of arterial blood escaping, shows that it has penetrated. The instrument may be directed to different points within the sac, and a drop or two deposited successively, forming as many centres of coagulation. On withdrawing the instrument, a turn of the piston, backwards, will prevent any of the solution escaping under the integument. This operative procedure is thus completed, easily and speedily.

Taking all these precautions, as to strength and quantity of the

† Compte rendu de l'Acad. des Sciences, 1845, vol. xxi.

‡ Sulla Elettropuntura nella cura degli Aneurismi, 1856.

solution and its injection into the sac alone, coagulation may proceed to consolidation and cure. But the process may stop short of this issue; or inflammation be excited in the sac, which, owing to the highly irritating character of the solution, will probably result in suppuration and sloughing, with fatal hæmorrhage, or by extending to the surrounding integuments, may end in gangrene of the limb. Thus, then, the probable consequences of this treatment restrict its eligibility; while the kind of coagulation induced *en masse*, disqualifies it proportionately, for the cure of aneurism. Then again the requisite compression of the artery on the cardiac and distal side, limits the applicability of injection to aneurisms in certain situations only. Internal aneurisms are excluded; and external aneurisms—those of the extremities—are open to far preferable methods of treatment—compression or ligature.

Injection seems to have been practised indiscriminately, or at least without regard to the situation of the aneurism. Originally suggested by Monteggia,\* injection was tried, with different coagulating agents, by Vilardebo,† Wardrop,‡ Leroy d'Etiolles,§ Pravaz, and Pétrequin.|| Aneurisms in every part of the body have been subjected to this treatment; those of the innominate artery, by Barrier; of the subclavian by Pétrequin; of the carotid by Dufour; and of the popliteal artery by Wiepce, Minor, Isaacs, and Lenoir. Aneurism of all sized arteries has been injected, from that of the supra-orbital artery, by Raoult and Deslongchamps; to the aorta itself, by Syme. The sum total at present exceeds thirty cases. But their results have not been sufficiently analyzed to draw any numerical conclusion for, or against, this kind of treatment. Injection succeeds in so far as it induces *coagulation*, rather than excites inflammation and its consequences. Such also is the favourable *modus operandi* of galvano-puncture.

TREATMENT OF TRAUMATIC ANEURISM.—The requisite operative procedures here also are governed by the pathology of this lesion.

In the first instance, traumatic aneurism is always a *diffused* and more or less pulsating collection of blood, communicating with an artery; this escape of blood having taken place, by a puncture or laceration, more or less complete, of the vessel; and with, or without, an external wound of the integuments. Such being the essential condition of traumatic aneurism; if the tumour be also enlarging—if it be *diffused*, and *diffusing*; the immediate and total arrest of the hæmorrhage, is necessary. For this purpose, no partial arrest of the current through the wounded artery—no mere retardation of the passage of blood, will suffice, as for idiopathic aneurism, in its early or circumscribed state. The *whole* force of the circulation through the artery, must be taken off, ere the hæmorrhage will cease, and the diffused aneurismal tumour cease to spread.

*Ligature*, therefore, of the artery *above and below* its wounded point, is the treatment indicated. This, however, is easier said than done, in most cases. A free incision into the tumour, will expose the half-coagulated blood and commingled textures, when the mass can be readily

|| *Bulletin de la Société de Chir.*, vol. iii. p. 524.

turned out; and recurrence of hæmorrhage during this procedure is guarded against, by an assistant compressing the artery on its cardiac side, and as near the tumour as is practicable. Having sponged the bottom of the cavity thus made; the bleeding orifice may be seen at once, or it will be discovered by a spirt of blood, when compression on the artery above is slightly, and momentarily, relaxed. This is the point for which the Surgeon seeks. The vessel must then be secured, by tying it on either side of the aperture; or if divided, by tying both ends. Here especially, difficulty is encountered; owing perhaps to inaccessibility of the artery, and also to its disorganized, although not degenerate state as in idiopathic aneurism. Failing to effectually control the hæmorrhage; plugging of the cavity, from the bleeding aperture outwards, will be necessary to completely arrest it. And this additional safeguard is unobjectionable, as the wound can only heal, for the most part, by granulating from the bottom.

If a traumatic aneurism has become *circumscribed*, thereby evincing a decided tendency to undergo the process of natural cure; then indeed the lesion so far resembling an idiopathic aneurism, it may be treated accordingly, by merely retarding the force of the circulation through the aneurismal artery. *Compression*, therefore, of the artery *above* the aneurism, or perhaps *direct* compression; and *ligature* on the *cardiac* side only, and at *some distance* from the tumour—*i.e.*, the Hunterian operation—are both eligible resources. If the circumscribed aneurism be of *small* size, compression alone may prove sufficient to retard the passage of blood; or that failing, the Hunterian operation will probably be an effectual check. This operation is often far more conveniently performed than any application of a ligature near the tumour. Thus, in the palm of the hand, where it would be difficult and hazardous to apply a ligature on either side of an aneurismal tumour, the brachial artery has been ligatured for a small circumscribed traumatic aneurism over the ball of the thumb, and cure was accomplished. (Erichsen.)

The application of a ligature, still on the cardiac side alone, but *near* the aneurism, is not forbidden by any structural condition of the artery. This procedure—Anel's operation—is appropriate, provided only that the force of the circulation through the aneurism can thus be sufficiently retarded. But, if the aneurism be, or become, of *large* size, although circumscribed; the force of the current preponderates over the arterial resistance, and the balance cannot be sufficiently restored by a ligature at any part of the artery, on its cardiac side alone. The treatment accordingly is again restricted to double ligature—one on either side of the bleeding aperture—by the operation already described; the old operation of Antyllus, as for *diffused* traumatic aneurism.

The treatment of traumatic aneurism unaccompanied by an external wound, will be considered in connexion with Complicated Fracture and Dislocation, respectively.

ANEURISMAL VARIX, AND VARICOSE ANEURISM.—*Structural conditions*.—An opening between an artery and a vein, in contact, whereby a *direct* communication of the two vessels is established, constitutes Aneurismal Varix. (Fig. 61.) Through this opening, the current of arterial blood, being the more forcible, passes, in part at least, into the opposing current of venous blood. Under favourable circumstances—to be presently explained—an *indirect* communication is established, by the formation of an intervening circumscribed false aneurism; this condition constituting

**Varicose Aneurism.** (Fig. 62.) It is so named from the varicose condition of the vein, with which the artery thence communicates. But the vein is varicose also in Aneurismal Varix.

FIG. 61.

FIG. 62.

*Signs.*—The same signs accompany either of these lesions, and they are very significant. Take, for example, a communication of the brachial artery and median basilic vein, occasioned by unskilful venesection; whereby both these vessels are punctured, as they cross at the bend of the elbow.

FIG. 63.

The superficial aperture in the vein and skin may soon have healed, but the deeper aperture in the vein and that in the artery remain open. The current of arterial blood being partly diverted from its course, is less forcible below the seat of injury, reducing the pulsation at the wrist to a feeble thread; and as the jetting stream passes through the median basilic vein into the veins of the forearm and arm, they become distended and tortuous, or varicose. The median vein, more especially, assumes an eel-like appearance down the forearm; while the median basilic and cephalic, the radial and ulnar veins, with the basilic and cephalic veins at the bend of the elbow, also exhibit in various degrees the force of the arterial current; they all become enlarged and varicose. (Fig. 63.) Aneurismal Varix simply, is formed, as the result of the puncture of both vein and artery; or, the jet of arterial blood passing into the vein, may burrow for itself a cavity in the intervening cellular tissue; forming a circumscribed false aneurism, as the medium of an indirect communication between the two vessels, and constituting Varicose Aneurism.

communication between the two vessels, and constituting Varicose Aneurism.

In either condition, the *varicose* state of the neighbouring veins con-

nected therewith, is the *earliest* and *most characteristic* appearance. The aneurismal swelling is wholly, or partly, formed, as the case may be, of enlarged and tortuous veins. And these veins, with, or without, the circumscribed aneurism, pulsate in unison with the arterial pulse; their pulsation being distinctly visible, perceptible also as a tremulous thrill, and audible as a soft, burring sound. Moreover, the whole swelling can be emptied by pressure upwards in the course of the veins, or it subsides and regains its former dimensions, when pressure is made on the artery. An elevated position of the limb will have the same effect. In the event of a circumscribed aneurism having formed, between the aperture in the artery and that in the vein; this portion of the swelling is at first soft and compressible, but it acquires a firmer and less elastic consistence, by the gradual deposition and consolidation of fibrine within the sac. If allowed to progressively enlarge, the skin shows the tint of venous obstruction, by assuming a livid hue; while the whole limb downwards from the seat of injury, becomes swollen, œdematous, feeble, numb, and cold, even threatening gangrene.

*Causes.*—The communication between an artery and a vein, is commonly of *traumatic* origin; as that produced by puncture in unskilful venesection at the bend of the elbow, or a lesion resulting from the thrust of a sharp instrument, or a ball in gunshot wound passing, between an adjoining artery and vein. But an opening may result from a diseased condition of the vessels, the lesion having an *idiopathic* origin; as in the bursting of an ordinary aneurism occasionally into a neighbouring vein. The *determining* cause of Aneurismal varix simply, or the formation of Varicose Aneurism, has reference to the anatomical relation of the artery and vein. Whenever the two vessels are in contact, a direct communication may be produced—giving rise to Aneurismal *Varix*; whenever the vessels are not in contact or in apposition, an indirect communication is established, by the formation of an intervening circumscribed false aneurism—constituting Varicose Aneurism. The latter is an additional condition. Aneurismal varix, or perchance, *plus* the intervening aneurism, may be produced in various parts of the body; wherever, a direct, or an indirect, communication can be established between an artery and vein of tolerable size. Therefore, with respect to the thigh, the ham, the neck, the arm, and in other situations, there are cases recorded. [P. p. 547.] But, the bend of the elbow, as already described, is the more common seat of these lesions, or it was so in the days of venesection.

*Course, and Consequences.*—Whether simply as Aneurismal varix, or as Varicose Aneurism, the vascular condition may remain stationary for years. There are cases of varix on record, which remained without further inconvenience for fourteen, twenty, and thirty-five years. But in all cases, the *tendency* is to gangrene of the limb or part, below the seat of communication between the artery and vein.

*Treatment.*—The more simple condition—*Aneurismal Varix*—requires treatment only in proportion to its progressive enlargement. In most cases, remaining stationary, for months or even years, and without any notable inconvenience, no remedial interference will be necessary.

The *prevention* of any further enlargement of the already aneurismally enlarged and tortuous veins, should be the first consideration. Moderate pressure, applied over the aperture of communication between the artery and vein, will, generally, be a sufficient restraint to counteract

any such tendency. A suitable compress should be worn, with an elastic bandage to support the veins below the aperture.

In exceptional cases, aneurismal varix undergoes *progressive enlargement*; at length attaining such size as to endanger the limb by gangrene, or the patient's life by hæmorrhage. Then indeed it becomes necessary to entirely stop the transmission of blood from the artery into the vein. No partial arrest, no mere retardation of the arterial current, will avail. Compression, whether applied directly over the aperture, or indirectly to the artery above the varix; or the Hunterian ligature applied higher up, would, therefore, alike be useless. The transmission of blood can be entirely precluded, only by cutting off all communication between the two vessels; namely, from above and below. Hence, the operation by double ligature of the artery, on either side of the aperture, is the only safeguard; the same as for a punctured wound of the vessel.

In the event of *Varicose Aneurism* having formed, this indication of treatment is the more imperative. A circumscribed false aneurism co-exists with the varix, and the sac has two apertures, placed also on opposite sides; thus freely transmitting a stream of blood continuously through the sac, and completely frustrating any tendency to the deposition of fibrine and spontaneous cure. Gangrene and hæmorrhage are both more imminent than in aneurismal varix.

*Operation.*—The application of double ligature under the circumstances of aneurismal varix, and of varicose aneurism especially, is attended with some slight difficulty. In either case, the considerable varicose enlargement of the vein, forming a fusiform pouch over the aperture in the artery, with tortuous eel-like communicating branches of vein, above and below, and the dilatation of the artery itself, above the aperture, together constitute a pathological condition which well-nigh effaces the mere surgical anatomy of, say—the bend of the elbow, in a case of aneurismal varix resulting from unskilful venesection. If an intervening aneurism be *superadded*, as between the brachial artery and median basilic vein, in the case supposed; if, in fact, there be a *varicose aneurism*, this pathological complication still further transforms the purely anatomical relations of the part. Thus, in performing the operation for double ligature, the first incision through the skin and which lays open the venous pouch, brings into view a cavity at the bottom of which an aperture is seen. But this is not the aperture for ligature; it leads into another cavity, the intervening aneurism, which must now, in its turn, be laid open, at the bottom of which there is another aperture, opposite to the former one; and that aperture, leading into the artery, is the one, on either side of which the vessel must be secured. The application of the ligature is often a proceeding of some difficulty also; owing to the dilatation of the artery on the cardiac side, and its equally contracted state below the aneurismal aperture. In an aneurismal varix from wound of the femoral artery and vein, Professor Pirrie found the former vessel enlarged to the size of a portion of small intestine.

Considering the difficulties of this apparently simple operation, it has been proposed, by Roux and Fergusson, to apply the ligatures without opening the sac.

The objection to any operation by double ligature, is the risk, that in curing the lesion itself, gangrene or hæmorrhage will more probably supervene, than when it is allowed to take its natural course.

Other kinds of treatment have been proposed, but less in accordance

with pathology, and practised, therefore, with less success. Thus, *galvano-puncture* has proved effectual; in one case, by Bosse, in another by Capeletti, but through suppuration; and a third instance of cure is recorded by Debout.\* The perchloride of iron *injection* was tried by Serres d'Alais, Jobert,† Vallette,‡ and Velpeau;§ in two cases only with complete success; in a third suppuration effected a cure; and a fourth case, was altogether unsuccessful.

## CHAPTER XXIV.

### ANEURISM, IDIOPATHIC AND TRAUMATIC, OF SPECIAL ARTERIES.

#### ARCH OF AORTA.

**ANEURISM.**—*Symptoms.*—In the *early* stage of aneurism affecting any portion of the thoracic Arch of the Aorta, the symptoms are singularly absent or equivocal. A bellows murmur, or an extension of the second sound of the heart over a certain area, with some dulness on percussion, may be the only discoverable symptoms to arouse suspicion. Any tumour or pulsation externally is quite imperceptible, excepting with reference to three portions of the arch.

1. *The anterior aspect of the ascending aorta.*—Pulsation may be perceptible by pressure between the intercostal spaces on the right side of the sternum, simulating the cardiac impulse, in addition and opposite to the seat of the true beat of the heart. As the aneurism increases, a tumour presents externally.

2. *The summit of the arch.*—A pulsating tumour appears behind the margin of the sternum, and rising into the neck, commonly towards the right side, may simulate aneurism of the brachio-cephalic or carotid arteries. But the tumour has no defined lower boundary, being continued downwards into the thorax; and impulse, with dulness on percussion and a bellows or whirring sound, are felt and heard there. I shall have occasion to again notice the diagnostic significance of these cervical aneurismal loculi or sacculations of the thoracic arch, in connexion with aneurisms of the innominate and carotid arteries springing from the arch, at the root of the neck.

3. *The posterior wall of the descending aorta.*—A pulsating tumour appears posteriorly, to one side of the spine or under the scapula, commonly on the left side, and attains the size perhaps of a man's head, ere it bursts.

Apart from these three situations of aortic thoracic aneurism; other aspects of the aorta, as for example, within the pericardium, or the concavity of the aorta, are so placed with relation to adjoining parts, that aneurism proves fatal before any pulsating tumour becomes perceptible.

*Pressure-effects*, therefore, vary with the particular situation of the aneurism, in its relation to surrounding parts, and according to its progressive size.

(1) *At the root of the aorta*, and particularly in the intrapericardial

\* Bulletin de Thérapeutique, 1847, p. 123.

† Bulletin de l'Acad. de Méd., 1854.   ‡ Ibid., May 23, 1859.   § Ibid. 1854.

portion; an aneurism can scarcely attain any size before death occurs, by rupture into the pericardium.

(2) At the *termination of the arch*, or the descending aorta; aneurism often attains considerable size without any particular pressure-effects. Dysphagia is, however, the special symptom, the œsophagus lying immediately to the right of the tumour.

(3) In the *concavity of the arch*, aneurism is beset with obstacles to its progress; notably, the bifurcation of the trachea, and either bronchus right or left, according to the inclining direction of the aneurismal enlargement. Dyspnoea is the urgent symptom, owing to the mechanical effect of pressure on the air tubes or pulmonary veins, or its influence on the left recurrent laryngeal nerve in its course round this portion of the aorta.

(4) On the *posterior aspect of the arch*, aneurism soon occasions dyspnoea, with, subsequently, dysphagia; the concurrence of these two symptoms, therefore, has diagnostic significance.

(5) At the *upper border, or convexity of the arch*, aneurism is attended with peculiar symptoms; cerebral disturbances, owing to interruption of the circulation through the carotid arteries.

(6) On the *anterior aspect of the arch*, aneurism is less productive of pressure-effects than in any other part; œdema, only, slowly supervening by compression of the innominate veins.

Pain is a symptom common to all these aneurisms, as it is to aneurism in general. While, therefore, it cannot be reckoned a special symptom, its character is in some respects peculiar. The pain may be piercing and intermittent or neuralgic; arising from pressure on the nerves—spinal or sympathetic. Affecting principally the left side, it darts up the side of the head and face, radiating down the arm to the elbow, through the chest, or piercing to the scapula. Or the pain may be grinding, burning, and continuous; owing to excavation of the tissues and bones. This kind of pain affects chiefly the right side of the chest. In every case, pain is a very early symptom, as compared with symptoms more special and characteristic.

*Diagnosis.*—The special symptoms thus indicated by the anatomical relation of these aneurisms, are variously combined; and, indeed, this sort of diagrammatic view of the aneurismal aortic arch is often modified so as to present the most perplexing cases of diagnosis; either as to the existence of aneurism, or the particular portion of the arch which may be affected. The former question can only be determined by the presence of a tumour, pulsating as an aneurism; and, therefore, with reference only to either of the *three* first-named portions of the arch, the part also being thus indicated. Presuming the existence of aneurismal tumour; the second question—as to its situation—may perhaps be solved by due consideration of the special symptoms of functional disturbance referable to the several *portions* of the aortic arch; which although less favourably circumstanced for physical diagnosis, are more conducive to the manifestations of functional disturbance. Fortunately, this differential diagnosis as to the part affected, guides the special prognosis more than it modifies the treatment of these *Aortic Aneurisms*.

*Treatment.*—The same principles which guide the treatment of aneurism in general, are here applicable, for the arrest, if possible, of thoracic aneurism in any part of the aortic arch; but any operative proceeding will obviously be out of the question.

ANEURISMS AT THE ROOT OF THE NECK.—*Diagnosis*.—These aneurisms are associated in virtue of their pathology, and their diagnosis. They are aneurisms of 1 the *innominate* artery, and 2 of the commencement of the *right common carotid* and *subclavian* arteries, respectively. Aneurism of the *thoracic* portion of the *left common carotid* or *subclavian* arteries, is unknown.

In the diagnosis of the aneurisms referred to, at the root of the neck, on the *right* side, the special symptoms of aneurisms of the aortic arch must be duly considered; but the difficulty will be to determine which of the three arteries is the seat of aneurism.

The observations of my colleague, Dr. Cockle—in his valuable contribution\* to our diagnostic knowledge of these aneurisms—are here to the purpose. “Whenever,” says he, “a pulsating tumour which involves the root of the neck to any extent is first submitted to observation, and is unaccompanied by a sufficiently accurate previous history, there is, generally a felt difficulty of diagnosis, whatever the actual *position* of the tumour may be. Such difficulty may occasionally arise from an inability to determine the real nature of the tumour, but most frequently (an aneurismal character being assumed), it consists in isolating the vessel engaged. The general rules laid down for guidance in this latter particular are based almost mainly upon the position of the tumour, and the relative state of the circulation in the corresponding arteries of the arm and neck.” These rules, as laid down by Mr. Wardrop, are as follow :—Aneurism at the root of the carotid artery, presents itself first, in the small triangular space between the heads of the sterno-mastoid muscle. Aneurism of the subclavian presents on the outer or cervical side; and, of the innominate, on the inner or tracheal side, of that muscle. Then again, the pulse in the radial or brachial artery, or in the carotid or temporal, is less on the aneurismal side of the body. Diminished pulsation in the neck may indicate aneurism of the carotid trunk; in the arm, that of the subclavian; while diminished pulsation in both situations, may indicate aneurism of the innominate artery.

But there are many exceptions to these general rules. Thus, the pulsating tumour of *aortic* aneurism may rise in the form of secondary sacculations ascending the neck, in the ordinary situation of innominate or carotid aneurism; and induce modifications in the circulation and sensibility of the right upper extremity. Or, instead of rising, an aortic aneurism may find its way amid the loose cellular texture of the thoracic mediastinum; but by compressing the innominate, carotid, or subclavian arteries, it will affect the pulse in the same situations as aneurism of these vessels.

Respecting *innominate* aneurism in particular; the differential diagnosis—observes Dr. Cockle—is attended with difficulties in tolerably direct proportion to the *part* of the trunk affected. “When the *origin* of the vessel is alone involved, it is—in his experience—invariably combined with aneurism, either true or false, of the ascending aorta. This form of innominate aneurism thus loses all individuality, and merges into the general pathology of aortic aneurism. It has absolutely no clinical history of its own. If, as at times, though with extraordinary rarity, an aneurism should limit itself to the *mid-portion* of the trunk and anterior wall, it may remain for a time, or even through its entire course, intra-thoracic, descending and moulding itself upon the aorta, evoking all

\* Med.-Chir. Trans., 1867.

the physical phenomena and symptoms of aneurism of the ascending and transverse aorta; or it may additionally, by one or more loculi, ascend the neck either on the tracheal or acromial side of the sterno-mastoid muscle. Should, therefore, a pulsating tumour with or without cervical extensions, occupy the space corresponding to the second and third costal cartilages of the right side and upper portion of the sternum, and present the ordinary symptoms of aneurism; though we may be practically safe in locating the disease in the aorta, it is not from any inherent difference of signs or symptoms, but from the rarity of intra-thoracic innominate aneurism.

"It is only when the *distal end* of the trunk becomes the seat of aneurism, that accuracy of diagnosis is attainable, though, in such case, the origins of the carotid and subclavian arteries often share the dilatation. Certain signs and symptoms are ascribed to innominate aneurism. Their value is high, in proportion as intra-thoracic disease can be eliminated; but extremely small, as the evidence for such disease increases. This is by far the most important point in diagnosis. The only possible source of error is the rare fact of an aortic sac arising from the convex wall of the arch, and mounting up the neck. Valuable aid is afforded by the knowledge of some antecedent local injury or violent and unusual effort; very many such cases being traumatic. These points determined; should severe pain of the right shoulder, clavicle, right side of the head, neck, and arm, with local venous congestion or œdema precede the appearance of a pulsating tumour, which, emerging from beneath the right sterno-clavicular articulation, and often displacing the head of the clavicle during its ascent, distends the space between the heads of the sterno-mastoid muscle, and fills the *epi-sternal notch*—should there be marked weakening of pulsation in the right radial and carotid arteries, pressure upon one or other artery loosening the impulse on the tumour—should a murmur, loudest over the tumour and at the sterno-clavicular articulation, diminish downwards, yet ascend the arteries on the right side, if pervious, such murmur being absent upon the left side; then, an aneurism of the *terminal* portion of the innominate artery may, with tolerable certainty, be diagnosed."

*Pressure-effects.*—Aneurisms of the innominate artery, and of the commencement of the carotid and subclavian arteries, produce the same pressure-effects—varying in degree—owing to their similar relations, for the most part, to surrounding structures. These effects have also a general resemblance to those produced by aneurisms of the aortic arch.

They are—dyspnœa, dysphagia, enlargement of the veins of the neck and right arm, with œdema, and pain.

*Dyspnœa* arises from the mechanical effect of pressure on the trachea, and in the case of innominate aneurism, possibly on the right bronchus; or from pressure on the right recurrent laryngeal nerve. The latter occasion of dyspnœa is accompanied with some husky modification of the voice, or loss of voice, paroxysmal cough and slight mucous expectoration. *Dysphagia* may be more or less complete. *Venous obstruction* is evinced by enlargement of the external jugular vein, the veins of the arm, and those below the clavicle in front of the right side of the chest. *Œdema* supervenes in the right eyelids, face, and head, and in the hand and arm. The *pain* has the usual heavy excavating character, in connexion with the tumour, and acute intermittent character from varying pressure on the cervical and brachial plexus of nerves; this pain shooting

up the right side of the neck, head, and face, spans the shoulder and front of the chest, and radiates down the arm to the hand. Some loss of muscular power in the right arm commonly supervenes.

The *diagnosis* from Tumours—not aneurismal—at the root of the neck, must be guided by the differential characters already described in connexion with ANEURISM.

*Causes.*—Aneurisms at the root of the neck are frequently traumatic; resulting from some violence, a blow, or strain in muscular exertion. Disease of the artery affected, predisposes, however, to the occurrence of such aneurism.

*Terminations.*—These aneurisms are invariably fatal, although in a variable period. The probable duration will depend on the particular direction the aneurism takes with relation to adjacent parts; and death occurs, usually by asphyxia, occasionally by rupture and repeated hæmorrhage.

*TREATMENT.*—Constitutional treatment—hygienic and medicinal as for Aneurism in general—is said to have proved successful in several instances. But, such resources having failed; the naturally fatal character of these aneurisms, renders the alternative consideration of operative proceedings unavoidable. Hence, the primary importance of a correct diagnosis of the particular vessel affected; either of the three vessels at the root of the neck, being, possibly the seat of aneurism.

1. *Innominate Aneurism.* — *Ligature*, on the *distal side*, may be resorted to; (a) of the subclavian artery alone; (b) of the carotid artery alone; (c) of both arteries. Neither of these modifications of Brasdor's operation for Aneurism has been followed by any notably successful results.

Distal ligature of the *subclavian* alone, has been practised in 3 cases; by Dupuytren, Langier, and Wardrop. The first two were fatal; the one on the 9th day from secondary hæmorrhage; the other, a month after operation, from asphyxia. In the third case, death occurred two years after operation, from exhaustion. The sac, in the first case, became smaller, the tumour diminishing, but its pulsations continued; in the second, the right carotid was obliterated by pressure of the tumour; in the third, the size and pulsation of the tumour diminished, but pulsation returned in the right carotid on the 9th day, thus apparently saving the life of the patient for two years. In any case, ligature beyond the *scaleni*, allows that portion of the current of blood through the aneurism to continue, which supplied the branches of the subclavian; namely, the superior intercostal, and internal mammary, the vertebral, and the thyroid axis. This direct transmission of blood in considerable quantity, not to mention that which passes off indirectly by the carotid artery, renders the probability of consolidation taking place in the sac, all but hopeless.

Distal ligature of the *carotid* alone, is not liable to this source of failure; no branch being given off from the parent trunk. The operation has been performed in 9 cases of innominate aneurism. In 8, a fatal result ensued in periods, varying from a few hours to a few days, or some months, even 20 months. Secondary hæmorrhage, asphyxia, and exhaustion, were apparently the causes of death consequent on the operation, excepting in two of the cases; one dying—a few hours after operation—from insufficient supply of blood to the brain; the other—on the 60th day—from hemiplegia. The only successful case, lived 34 years,

and possibly longer. The sac, in these cases, underwent consolidation in various degrees, the tumour and its pulsation diminishing accordingly; but this reparative change seemed to have no proportionate relation to the period after ligature. Thus, in one dying on the 7th day, the tumour was nearly filled with firm laminated coagulum; whereas, in another, on the 115th day, no alteration in the tumour had taken place. Suppuration in, and rupture of, the sac, occurred in one case; and also in the only case of recovery.

Distal ligature of *both* the carotid and subclavian arteries has been practised in four cases, by Fearn, Wickham, Rossi, and Christopher Heath. In the first two, the vessels were ligatured successively; an interval of two years, or of two months, elapsing between the operations. In the third case, the vessels were ligatured simultaneously. All were fatal; the first dying in three weeks after second operation, from pleurisy; the second, two and a half months after first bursting of the sac. The third case was fatal in six days, but remarkable for the patient having survived that time; the supply of blood to the brain being wholly cut off, otherwise than through the left vertebral artery. The sac in the first of these four cases—*i.e.* after two years—was found filled with dense organized coagulum; except a channel of the size of the artery, for the passage of blood. In the second case, the tumour diminished, after ligature of the carotid, but increased after ligature of the subclavian.

2. *Aneurisms of right carotid, and subclavian, arteries, at their origin—the root of the neck.*—*Ligature of the innominate artery.* This operation, in principle, applicable to either of these aneurisms, is impracticable in some cases; and has been fatal in its result with regard to all the cases in which it has hitherto been practised. Eleven such cases are recorded, the operation having been commenced but not completed in four other cases. All the eleven were fatal. Of these: 9 were cases of subclavian aneurism, the remaining 2, aneurism of both the subclavian and carotid arteries. In the former cases, death took place in periods, varying from the 5th day to the 67th day; and, with scarcely an exception, from secondary hæmorrhage; one died in 12 hours, also from hæmorrhage; but this case was a punctured wound in the axilla, for which the subclavian was ligatured and then the innominate artery. In one case only, on the 8th day, death resulted from inflammation of the aneurismal sac, lung and pleura. In the 2 cases of double aneurism, death occurred on the 9th and 34th days, but in both from accidental causes. In the 4 incompleated cases, the operation-difficulties were apparently, the large size of the aneurism, or the diseased state of the innominate.

*Carotid aneurism alone*,—at root of the neck. *Distal* ligature of the artery. Six cases are recorded by Norris;\* in 4 of which, the result was successful. This proportion is sufficient to justify a repetition of the operation, under favourable circumstances. In one case of traumatic aneurism of the carotid—at the root of the neck—arising from a stab in that situation, Mr. Syme performed the *old* operation for Aneurism; that of puncturing the sac, feeling with the finger in the sac for the aperture which controlled pulsation, then turning out the coagulum from the sac laid freely open, and securing the vessel by ligature above and below the aperture.

\* American Journ. Med. Sciences, vol. xiv.

*Subclavian aneurism alone*, at the root of the neck—*i.e.* situated either internal to, or between, the scaleni.—*Distal* ligature of the artery, in the *third* part of its course.—This operation has been proposed, but I am not aware that it has ever been practised.—The axillary artery below the clavicle, under the pectoral muscles, was ligatured by Dupuytren for subclavian aneurism; and this distal operation proved fatal, on the 9th day, from hæmorrhage. *Amputation* at the shoulder-joint, with, therefore, distal ligature of the artery, was suggested by Sir William Fergusson; the presumed advantage being, that the tumour might then be much more under the control of pressure, as the supply of blood below would no longer be requisite. This suggestion has not yet been tried; except in a case, by Mr. Spence of Edinburgh, and with a temporarily favourable result.

#### CAROTID ARTERY.

**ANEURISM.**—*Symptoms.*—The usual symptoms of an aneurismal tumour are present, and well-marked, owing to the situation of carotid aneurism. The pressure-effects are similar to those of carotid, subclavian, and innominate aneurisms, at the root of the neck, and those also of aneurisms of the aortic arch; so far as their anatomical relations are similar. Thus, the contiguity of the tumour to the trachea and œsophagus gives rise to increasing dyspnœa and dysphagia; compression of the recurrent laryngeal nerve occasions hoarseness or loss of voice; pressure on the cervical plexus is accompanied with some pain or loss of sensibility in the parts thence supplied; and there may be some giddiness or other cerebral disturbance, owing to interruption of the circulation through the aneurismal artery.

The *diagnosis* of carotid aneurism must have regard to the various kinds of pulsating tumour which are liable to occur in connexion with the carotid artery. Enlarged lymphatic glands, and tumours, especially cysts, and abscess, situated on, or communicating with the artery; may severally simulate aneurism.—They are all pulsating swellings; but differing in the less expansive character of the pulsation, and the incompleteness possibly, of the supposed aneurism. The history of the case will aid the diagnosis, as in that of abscess. The fluid, as well as the pulsating, character of any superimposed cyst or abscess, or when communicating with the artery, and virtually forming an aneurism, are the two conditions which require the utmost caution in diagnosis. Mr. Liston, once inadvertently punctured a cervical abscess, which, communicating with the carotid artery, had thus become converted into aneurism. Pulsating tumours present even more perplexing difficulty. Pulsating enlargement of the thyroid body differs from a supposed aneurism, in its situation, and more particularly, in the tumour moving up with the trachea in the act of deglutition. Any tumour, *not* communicating with the carotid artery, can be raised from the vessel, when the aneurismal symptoms will be found to cease; excepting the thrill of a pulsating tumour. Aneurismal varix of the internal jugular vein is an occasional question of diagnosis. In addition to the ordinary signs of varix, the notable diminution of the tumour during a deep inspiration, will perhaps determine the question.

*Causes.*—Carotid aneurism—unlike the aneurisms hitherto noticed, and in particular, innominate aneurism—is rarely traumatic. Hence, probably, the fact, that it occurs more frequently in the female than any

other external aneurism. In 25 cases, 12 were in women. But the comparatively early age at which it may occur is remarkable; in one instance, a girl of ten years, in another, of eighteen. The right carotid is more commonly affected than the left, and the upper portion of the vessel than the lower; the bifurcation being the chosen seat of carotid aneurism.

*Course and Terminations; and Prognosis.*—An unfavourable career may generally be predicated, owing to the proximity of carotid aneurism to the central force of circulation—the heart—and also its important anatomical relations in the neck. Rupture, with recurrent hæmorrhage, is one mode of termination; the tumour bursting externally, or into the pharynx or œsophagus. Asphyxia, by pressure on the larynx and recurrent nerve, is another termination. Starvation, by compression of the œsophagus, is yet a third issue, but not so imminent as either of the others. The particular part of the artery affected will materially modify the issue, and the duration of the case. It may be said generally, that the more distant the aneurism from the root of the neck, the less perilous are its pressure-effects, and the less imminent is any mode of fatal termination. Aneurism at the bifurcation of the carotid, below the angle of the jaw, may thus continue for years. At last, however, further want of space renders the contiguity of important parts increasingly perilous.

*Treatment.*—*Ligature*, on the *cardiac* side of the artery. This operation has certain important consequences relating to the brain, the lungs, and the aneurism.

In 149 cases—tabulated by Dr. Norris—54, or more than one-third, died. Of these, secondary hæmorrhage was the cause of death in 15 cases; gangrenous softening of the brain, with various disturbances of the cerebral functions, in 12 cases. The latter consequences evidently depend on the seriously diminished supply of blood to the brain by ligature of the common carotid trunk, leaving only the vertebral artery to carry on the circulation in the same half of the brain. The free anastomosis of arteries at the base of the brain—constituting the circle of Willis—does not seem to sufficiently compensate for this deficiency. But the consequences will of course be doubly perilous, if both common carotids be ligatured. The *symptoms* of cerebral disturbance are giddiness, paralysis, blindness, deafness, and convulsive movements; followed by stupor, coma, and death. Inflammatory symptoms sometimes follow the operation. Softening of the brain ensues from mal-nutrition depending on defective circulation. The *frequency* of cerebral symptoms is attested by the statistics of Ehrmann. Of 187 cases, in which one carotid was tied, 42 were followed by some kind of cerebral disturbance. In 213 cases—including ligature of both carotids, and those of the innominate artery—cerebral symptoms ensued in 47, or about 22 per cent.

The following conclusions—according to Mr. Erichsen—seem to be established. (1) Ligature of one carotid artery is followed by cerebral disturbance in about one-fifth of the cases, more than one-half of which are fatal. (2) Ligature of both carotids simultaneously, has always proved fatal; as in the two cases in which Mott and Langenbeck ligatured these vessels, an interval of only a few minutes elapsing between each operation. (3) Ligature of both carotids, an interval of some days or weeks elapsing, is not more frequently followed by cerebral disturbance than when only one is tied. (4) Obliteration of the vessels taking place gradually and successively, the patient may live; although one carotid

and one of the vertebrals have been occluded by disease and the other carotid ligatured, as in the case related by Rossi. (5) Occlusion of both carotids and both vertebrals, may yet allow life to continue for a considerable period, as in a case recorded by Dr. Davy; the cerebral circulation being maintained through the medium of the anastomoses of the intercostals and internal mammary arteries.

Congestion and inflammation of the lungs, is another affection not unfrequently consequent on ligature of the carotid. The explanation of this condition is difficult. It may arise from deficient influence of the brain or medulla oblongata in its relation to the respiratory movements. Suppuration of the sac is apt to occur as with other aneurisms, and even some weeks or months after the application of the ligature. Secondary hæmorrhage is another untoward event.

Recurrence of pulsation in the sac, soon after ligature of the common trunk—on the cardiac side—is not an uncommon nor unfavourable event. It would appear to depend on the free communication of the arteries from the opposite side of the brain, returning blood through the branches of the internal carotid above the sac. A collateral circulation, however, becomes established through branches of the subclavian on the same side. Thus, in a case related by Porter, after ligature of the right carotid, the subclavian and vertebral arteries were enlarged to double their normal diameters; the latter artery supplying the function of the internal carotid, and the inferior thyroid communicating freely with the superior thyroid artery.

WOUNDS, and TRAUMATIC ANEURISM, of the *Carotid Artery*.—*Ligature*, immediately above and below the seat of wound, is the appropriate operative procedure, as in wounds of other arteries.

ANEURISMAL VARIX of the *Carotid Artery and Jugular Vein*.—Resulting from punctured wounds in the neck implicating both these vessels, and in one instance, related by Mr. Macmurdo, consequent on disease; the signs, and the stationary character of this condition, are not peculiar to varix in this situation. No operative interference is requisite.

#### INTERNAL CAROTID.

EXTRA-CRANIAL ANEURISM.—*Symptoms*.—The internal carotid before its entrance into the carotid canal, may be the seat of aneurism. In situation, therefore, it nearly corresponds with aneurism of the common carotid at its bifurcation; but that of the internal carotid is situated under, or more immediately below, the angle of the jaw. The symptoms, also, are similar to those of common carotid aneurism, but there is a greater tendency to extension of the tumour inwards towards the pharynx, the direction of least resistance.

*Diagnosis*.—Internal carotid aneurism may thus simulate abscess of the tonsil. The marked pulsation of the tumour in its pharyngeal aspect, which can be both seen and felt expanding with each beat into the mouth, will principally determine the diagnosis.

*Treatment*.—*Digital pressure* on the common carotid, should be tried in the first instance. *Ligature* of that artery is the only available operative procedure, subsequently. Its results are uncertain.

INTRA-CRANIAL ANEURISM.—*Symptoms*.—Within the cranium, aneurismal dilatation of the internal carotid may occur in either of the three parts of its course; (1) in the carotid canal; (2) in the cavernous sinus; (3) in relation to the brain. Aneurisms of the other cerebral arteries

are conveniently associated with that of the carotid in the latter situation.

Of 62 cases noticed by Dr. Gull, the vertebral arteries and their branches were the seat of aneurism in 28, and the carotids and their branches in 34. The basilar artery was affected in 20 cases, and the middle cerebral in 15. In 8 cases, the internal carotid within the cavernous sinus was affected, and in 6 others the anterior cerebral artery.

(1) In the *cavernous sinus* the symptoms are mainly, those of aneurism, of pressure on the orbital nerves, and of disturbance of the cerebral circulation. Thus, arising, probably, from a blow or other injury, the person who is the subject of cavernous carotid aneurism, hears a sharp crack, followed by a sawing or rasping noise, which may also be heard by the stethoscope applied to the head or neck; but this sound ceases when pressure is made on the common carotid of the side affected. No tumour can be discovered externally. Pressure on the orbital nerves is announced, either by internal strabismus from paralysis of the sixth nerve,\* or by ptosis with external strabismus and dilated pupil from pressure on the third nerve,† or by loss of sensation in the parts supplied by the supra-orbital nerve.‡ The sense of vision usually remains unimpaired, or there may be double vision or other defect of sight. These affections of the orbital nerves exist singly or in combination. Cerebral disturbance is evinced by giddiness, headache, a sensation of fulness on stooping, and sleeplessness or disturbed sleep.

*Diagnosis.*—Similar symptoms may arise from any occasion of pressure on the artery in the sinus; as by coagula formed in the ophthalmic vein, the cavernous, circular, transverse, and superior petrosal sinuses. Otherwise the diagnosis of cavernous carotid aneurism can be made with tolerable certainty.

*Intra-orbital aneurism* is associated in point of situation and origin; the aneurism springing from the carotid artery, or, in some cases, from the ophthalmic branch. Anastomotic aneurism, or erectile tumour within the orbit, is an *independent* formation, and occurs more rarely; thus differing in its pathology from that of intra-orbital aneurism which was formerly regarded as an erectile growth. Mr. Busk§ has shown that many of these true aneurisms are traumatic; and Mr. Nunneley maintains that all are ordinary spontaneous or traumatic aneurisms, except those which have spread into the orbit from a *nævus* of the face.

*Diagnosis.*—The following general distinctions are adduced in evidence of this view:—Aneurism by anastomosis comes on gradually, mostly in early life, as the result of the growth of a congenital *nævus*; aneurism of the orbit very suddenly, often as the result of a blow, and almost always in advanced life; aneurism by anastomosis occurs in the sub-cutaneous tissues; aneurism of the orbit generally in the deepest part of the cavity; aneurism by anastomosis involves all the neighbouring vessels, arteries, and veins, in active disease; aneurism of the orbit is generally limited to a single part, or if the neighbouring vessels are dilated, they seem only enlarged from obstruction; ligature of the trunk of a vessel leading to an undoubted aneurism by anastomosis is an extremely unsuccessful operation; in aneurism of the orbit a very successful one; lastly, the cases dissected have turned out to be common

\* British Med. Journ., 1855.

† Path. Soc. Trans., vol. xii.

‡ Ibid.

§ Med.-Chir. Trans., vol. xxii.

aneurism. The diagnosis of *anastomotic* aneurism may perhaps be determined—as in Travers' and Dalrymple's cases—by the presence of soft, compressible, thrilling tumours in various parts of the eyelids; collections of veins apparently, transmitting pulsation from the subjacent aneurism.

(2) *At the base, or in the substance of the brain*, aneurism of the cerebral branches of the internal carotid, or of other cerebral arteries, is liable to occur. The symptoms, if any, are very equivocal; pressure arising possibly from other causes than cerebral aneurism, and the diagnosis, therefore, is equally obscure. The sensation of a sawing or rasping noise in the head, varying with the circulation, and which probably has supervened shortly after some injury, may be suggestive of aneurism; a suspicion corroborated, perhaps, by careful auscultation of the head, leading to the detection of a bruit.

*Diagnosis.*—Symptoms referable to pressure may arise from any other tumour; and similar symptoms ensue from softening of the brain. Hence, general or partial paralysis, blindness, deafness, or other affections of the special senses; are symptoms of an equivocal character.

*Causes.*—A blow, a fall, or other traumatic mode of origin can be traced, in some cases; in others, the symptoms seem to arise spontaneously, without any previous ill-health. The cerebral arteries are said to be healthy, in most cases; but this is improbable. Age notably affects the liability to intra-cranial aneurism; the tendency increasing as life advances. Of 58 cases, in 12 only this condition occurred under twenty-five years of age, 5 of whom were under twenty; but of the remaining 46 cases, 13 occurred in persons under forty, 29 between forty and sixty, and 4 in persons above sixty. Sex seems to be predisposing, probably in connexion with occupation. Of the 58 cases, 35 were males, 23 females.

*Course and Terminations.*—The pressure of an intra-cranial aneurism is followed by softening of the portion of brain, or cranial nerve, in contact; and, possibly, absorption of any opposing portion of bone. The symptoms of paralysis supervene. Death ensues, by hemiplegia, or apoplexy by rupture of the aneurismal sac; the latter mode of death occurring more frequently in earlier life. According to Dr. Gull's table, in 20 cases of persons under thirty-five years of age, 16, or 80 per cent. died from rupture of the sac; while in 37 cases above thirty-five years, 14 or 38 per cent. only, terminated fatally in this way.

After death, much of the pathology of these aneurisms is made known by internal examination which could not be discovered during life, clinically, and which, therefore, cannot be applied in diagnosis. Generally, the aneurism is found to be a dilatation of the whole circumference of the artery, rather than a truly sacculated portion. Coagulation and the deposition of laminated fibrine, may have proceeded to the almost complete spontaneous cure of the aneurism. Usually not larger in size than a pea or Barcelona nut, the aneurism is sometimes much larger, having attained the size of a walnut or hen's egg. Rupture may have occurred in quite the smaller-sized aneurism. One aneurism only is found, rarely more. Thus, in one case, both carotids were dilated into bulbs occupying the hollow on each side of the sella Turcica, and which were filled with laminated coagulum. The preparation is in the museum of the College of Surgeons.

*Treatment.*—*Digital pressure* on the common carotid artery, may be

sufficient to overcome the symptoms wherever intra-cranial aneurism is situated; and it has also proved successful in intra-orbital aneurism, under the care of Gioppi and Vanzetti. When this method of treatment has failed, *ligature* of the common carotid is the only known resource. It was signally successful in the case of a woman aged fifty-five, under Mr. Coe, of Bristol.\* After ligature of the left carotid, the cranial bruit ceased, a gentle continuous murmur followed, due apparently to the flow of blood through the tumour from the anastomosing branches; this subsided in about five hours, and all the symptoms ceased permanently. Great success has attended this operation in intra-orbital aneurism. Out of 20 cases, 14 were successful, 2 partially so, in 1 the pulsation continued, and 3 died. In other 13 cases, 12 were cured. A case is also related by Mr. Hart,† of arterio-venous aneurism in the orbit which was thus cured. Digital pressure would seem to be at least advantageous in any case, as preparatory to ligature; dilatation of the collateral arteries preventing the otherwise untoward symptoms which are apt to follow the latter proceeding.

WOUNDS, and TRAUMATIC ANEURISM, *of the Internal or External Carotid, and their branches.*—*Ligature above and below* the seat of wound, may, perhaps, be impracticable, owing to the situation of the wounded vessel; or having failed to permanently arrest the hæmorrhage, the *common carotid* must be tied. The latter operation has certainly been successful in some cases. Traumatic aneurism having formed, will, of course, render ligature *in situ* more difficult; but even here branches of either carotid, situated superficially, may be thus secured. The temporal artery, for example, has been wounded in cupping on the temple, and given rise to traumatic aneurism; but as being a distal branch of the external carotid and readily accessible, the tumour can be laid open, its contents turned out, and the vessel tied on either side of the aperture.

#### SUBCLAVIAN ARTERY.

ANEURISM.—*Symptoms.*—Aneurism of the subclavian artery presents a pulsating tumour situated immediately *above* the clavicle, and commonly external to the margin of the sterno-mastoid muscle, the third part of the subclavian usually being affected. Its apparent size varies with the position of the shoulder, for the tumour disappears partly below the clavicle when the shoulder is raised. Pressure on the brachial plexus is accompanied with pain, and numbness down the arm even to the fingers; and the phrenic nerve also sometimes becoming disturbed, there may be spasmodic action of the diaphragm—hiccup, as an occasional symptom. The external jugular and subclavian veins suffering compression; œdema, particularly of the hand and arm, will be conspicuous in most cases.

*Diagnosis.*—Other tumours may occasion similar symptoms; their *differential* characters, compared with those of aneurism, should therefore be remembered in considering the diagnosis. (See TUMOURS IN THE NECK.)

*Causes.*—A traumatic origin can, generally, be traced—*e.g.*, a blow, fall on the shoulder, or violent muscular exertion of the arm. Hence, the more frequent occurrence of subclavian aneurism on the right side, and, perhaps, in connexion with an occupation requiring constant use of the right arm; and, certainly, the far greater liability of males

\* Brit. Med. Journ., 1855.

† Lancet, March, 1862.

than females. In 32 cases, 2 only occurred in females, and both from injury.

*Course and Terminations.*—Slowly increasing in size, the tumour ultimately attains large dimensions; occupying the space between the clavicle and trapezius muscle. Never passing inwards, the trachea and œsophagus escape pressure; neither dyspnœa nor dysphagia supervene. But the tumour may extend somewhat downwards, and thus encroach on the apex of the lung. Extending yet further, upwards or downwards, the aneurism bursts externally, or internally with hæmorrhage into the pleura. Rarely, subclavian aneurism undergoes a spontaneous cure; the sac becoming consolidated with laminated fibrine.

*Treatment.*—*Ligature of the subclavian*, on the cardiac side, in the *first* part of its course. This operation has been practised for the cure of subclavian aneurism—in the third part of the vessel—*i.e.*, beyond the scaleni, and when situated between these muscles—the second part. In the 8 cases recorded, all were fatal, in periods varying from the 4th to the 13th and 36th day; and uniformly from hæmorrhage, excepting in one case, where death occurred from pericarditis and pleurisy.

Ligature of the *innominate* artery, has also been fatal in every instance. The results of the 11 cases in which this operation was performed, have already been noticed. Nine were cases of subclavian aneurism, the remaining two, aneurism of both the subclavian and carotid arteries. (See Aneurisms at the root of the neck.)

*WOUNDS, and TRAUMATIC ANEURISM, of the Subclavian.*—Punctured wounds are occasionally met with, as a sword-thrust, or stab with a knife. Such a wound of the subclavian artery is usually fatal, before sufficient time has elapsed for traumatic aneurism to arise.

ANEURISMAL VARIX *of the subclavian artery and vein*, has been known to occur, in like manner.

#### AXILLARY ARTERY.

ANEURISM.—*Symptoms.*—The situation of the pulsating tumour of Axillary Aneurism is characteristic. It arises immediately *below* the clavicle, under the great pectoral muscle, or under the anterior fold of the axilla, if the second, or third, portion of the artery be the seat of aneurism. Pressure on the brachial plexus occasions pain and numbness extending down the arm and hand; œdema of the upper extremity also occurs from pressure on the axillary vein. But, the situation of the tumour distinguishes it from subclavian aneurism, a very important distinction as to the portion of artery eligible for ligature.

*Diagnosis.*—Other tumours may be recognised by their *differential* characters. An abscess pulsating over the subjacent artery, resembles aneurism in situation, but differs in the antecedent symptoms of inflammation. Pulsating tumour of the head of the humerus resembles aneurism in symptoms varying only in degree, but differs in situation, for it presents on the front of the shoulder.

*Causes.*—A blow, or fall, on the shoulder, violent movement, or other injury, to the joint; is the mode of origin traceable in most cases. Forceful extension in the endeavour to reduce old-standing dislocations of the shoulder, has furnished some instances of axillary aneurism, by rupture of the artery with the adhesions betwixt it and the bone. The traumatic origin of the aneurism renders its occurrence more frequent

on the right, than the left, side; and more common in men than women. Of 37 cases, 3 only happened in females.

*Course and Terminations.*—Enlarging rapidly in the loose cellular texture of the axilla, the aneurism extends downwards and forwards; occupying the whole axillary space, and thus acquiring a larger size than aneurism in most other situations. Or it may take an upward direction, elevating the shoulder, or projecting above the clavicle into the angular space between it and the trapezius muscle. At length, rupture takes place, externally, or internally into the pleura or lung. Spontaneous cure has never been known to occur.

*Treatment.*—*Compression* of the subclavian, in the third part of its course; may be either impracticable, owing to elevation of the shoulder or the projection upwards of the tumour, or it will be unendurable, owing to the unavoidable compression of the brachial plexus.

*Ligature* of the subclavian, in the *third* part of its course. This operation is the only resource, but its results have been most disastrous. In 48 cases of axillary aneurism, unconnected with any external wound; ligature of the third part of the subclavian terminated fatally in 25, while 23 were cured, a nearly equal proportion, or only 1 in 2. The causes of death consequent on the operation were, in some respects, peculiar. Inflammation within the chest in 10 cases; suppuration of the sac, in 6; hæmorrhage in 3; suppurative phlebitis, 1; gangrene of hand and arm, 1; general gangrene, 1; not stated, 3. If we extend the statistics of this operation to all cases, including ligature for aneurism, the results are equally discouraging. Of 69 cases, tabulated by Norris,\* 33, against 36, died, about the same proportion as after the operation for aneurism. In 6 cases, more recently,† operated on in London, 2 only recovered. Porta's table of 74 cases, is slightly more favourable than the returns of the same cases by Norris, *minus* the few additions. But the average mortality of ligature of the subclavian in the third part, in all cases taken indiscriminately, would appear to be considerably above 40 per cent.!

*WOUNDS, and TRAUMATIC ANEURISM, of the Axillary Artery.*—*Ligature*, *above* and *below* the puncture in, or division of, the vessel, is the appropriate operation. It was performed by Mr. Syme‡ in a case of ruptured axillary artery. Ligature of the artery *below the clavicle*, or of the *subclavian* above, must be had recourse to in cases where the previous operation is impracticable, owing to the great depth of the artery or other operative difficulty, or in the event of secondary hæmorrhage. Of 15 cases in which a ligature was applied below, or above, the clavicle; 9 were successful, and 6 died.

#### BRACHIAL, RADIAL, AND ULNAR ARTERIES.

*ANEURISM.*—The axilla is the limit below which spontaneous aneurism rarely occurs in the upper extremity. But it has been met with in the brachial artery, and in this vessel at the bend of the elbow; in the radial and ulnar arteries, and as low down as the ball of the thumb. Aneurism in any such situation is readily recognised by the ordinary symptoms, and can scarcely be mistaken for anything else.

*Causes.*—Some injury is usually the immediate cause, but the vessel, probably, was previously diseased. This was the condition in an aneu-

\* Amer. Journ. Med. Science, 1845.

† Med. Times and Gaz., 1856, vol. ii., 1860, vol. i.

‡ Med.-Chir. Trans., vol. xliii.

rism of the upper part of the ulnar artery, under the care of Mr. De Morgan at the Middlesex Hospital. The traumatic origin of these aneurisms can generally be discovered in their history. An old ship-carpenter, whilst at work, felt as if something had snapped in his arm. Mr. Liston ligatured the brachial artery. Aneurism of the radial artery at the ball of the thumb has followed an attempted reduction of dislocation.

*Course and Termination.*—These aneurisms rarely attain any considerable size, and may undergo a spontaneous cure. An aneurism of the radial artery, in a patient under Mr. De Morgan, recovered spontaneously.

*Treatment.*—*Compression* of the artery above the aneurism, is available wherever the situation offers ready resistance, and it can be borne. As regards the brachial artery; the round form of the humerus, and the nerves of the brachial plexus, forbid compression. *Digital pressure* may be available; and in the aneurism referred to, of the ulnar artery, this mode of compression maintained by the patient himself as long as he was able for several days, much reduced the size and pulsation of the tumour. On all these aneurisms, compression tells more effectually than in those of larger sized arteries.

*Ligature* of the artery, above the aneurism. Thus, the brachial may be tied for aneurism at the bend of the elbow; the ulnar or radial for aneurism of these arteries; and the latter, if the aneurism be situated at the ball of the thumb. Ligature of the brachial artery is usually very successful as regards the issue of the operation itself. In 68 cases—tabulated by Porta—10 died after the operation, but whether in consequence of it is uncertain.

WOUNDS, and TRAUMATIC ANEURISM of these Arteries.—These lesions are as common as spontaneous aneurism of the same vessels is rare.

The *Treatment* is the same as for similar lesions of other arteries.

*Double ligature* of the vessel at the seat of injury; or that failing, *ligature* of the artery *above*. *Compression*, by means of a graduated compress, applied in the seat of wound, or above, if an aneurism have formed, might be tried in the first instance; but it will rarely prove sufficient to permanently arrest the hæmorrhage. This method of treatment is most successful in wounds of the palmar arch, there being a steady resistance to the compress by the metacarpal bones. But it may become necessary to tie the radial and ulnar arteries, and subsequently even to ligature the brachial.

ANEURISMAL VARIX, AND VARICOSE ANEURISM.—These conditions mostly occur at the bend of the elbow; the brachial artery and median basilic vein communicating, by puncture in unskilful venesection. Seldom met with, therefore, in these days of almost abandoned general blood-letting, the rules of treatment should still be remembered in the event of any such accident happening.

*Compression*, with an accurately applied compress and roller, over the puncture, will generally succeed in restraining aneurismal varix. But, after considerable enlargement of the vein—varix being established, or the formation of an intervening sac—varicose aneurism; it will be necessary to completely cut off the current of arterial blood, by *ligature* of the artery on either side of the aperture of communication.

Any other operative proceeding would be ligature of the arterial trunk *above*; an alternative rendered necessary only by impracticability of the operation *in situ*, and which is not so directly effectual.

### ABDOMINAL AORTA; AND ILIAC ARTERIES, COMMON, INTERNAL, AND EXTERNAL.

**ANEURISM.—Symptoms.**—The symptoms of abdominal or pelvic aneurism, are similar to those of aneurism in other situations. A tumour, the pulsations of which can be felt, heard, and perhaps seen externally; compressible, and subsiding if pressure can be made on the arterial trunk above. The pressure-effects are various, according to the relations of the tumour to adjacent viscera; pain also and œdema supervene as the nerves and venous trunks suffer compression. Thus, in parts supplied by the lumbar plexus, pain is experienced—*e.g.*, down the thigh and leg, if the anterior crural nerve be stretched over the tumour; while œdema of the limb is occasioned by pressure on the vena cava, common or external iliac veins.

**Diagnosis.**—Other tumours may give rise to analogous symptoms.

Internal *abscess*, pulsating perhaps, in connexion with the aorta or iliac arteries, must be remembered as an occasional source of serious error in diagnosis. The distinction between abdominal or pelvic aneurism and *pulsatile tumours of bone*, is most difficult.

The following characters seem to be generally distinctive, though seldom or never present collectively. In pulsatile tumours of bone; (1) the bruit is less marked or absent; (2) the pulsation is more sudden, less heaving and expansive, and equally forcible whether the tumour be large or small; while in aneurism, the force of pulsation is proportionate to the size of the tumour; (3) The bone connected with a pulsatile tumour is expanded, thus presenting a considerable osseous enlargement around the seat of disease—*e.g.*, the ilium on either side of a tumour developed in it; an aneurism simply eating an aperture, the margin of which may be felt if the tumour can be made to collapse. Osseous swelling determined the diagnosis of a pulsatile tumour of the ilium, in St. George's Hospital; the tumour projecting at the sacro-sciatic foramen and simulating aneurism of the gluteal artery. In a case recorded by Mr. Stanley,\* a plate of bone was found in the walls of the tumour; (4) Pulsatile tumour of bone is very commonly cancerous, and accompanied therefore with other evidence of this disease.

The *seat* of abdominal or pelvic aneurism—*i.e.*, the particular artery affected—will obviously be an important consideration in relation to treatment by any operative proceeding.

**Treatment.**—*Compression* of the artery above the aneurism, is practicable only in very thin persons, and those who can bear prolonged compression of the aorta against the vertebral column. It can be effected, instrumentally by means of a pad-compressor, or by digital pressure.

**Ligature of the abdominal Aorta.**—This desperate operation has been practised in 5 cases. By Sir A. Cooper, in 1817; and subsequently, by James, of Exeter; by Murray, at the Cape of Good Hope; by Monteiro, at Rio Janeiro; and by South, of London. All the cases were fatal, and as the result of the operation; the 1st case, dying in 40 hours; the 2nd, in the evening of the operation day; the 3rd, in 23 hours; the 4th, on the 10th day; and the 5th, in 43 hours.

Such having been the unexceptional fatality of this operation, the particulars of the cases themselves are comparatively unimportant. Sir

\* Med.-Chir. Trans., vol. xxviii.

A. Cooper's case was an aneurism of the left common iliac artery and some portion of the vessel below. Mr. James's case was *inguinal* aneurism, for which he had previously performed the distal operation. Monteiro's case was a large false aneurism in the lower and right side of the abdomen; the patient dying—on the 10th day—from secondary hæmorrhage.

*Ligature of the common iliac.*—This operation has not been uniformly fatal in its results. In 32 cases, collected by Dr. Stephen Smith,\* 25 died, 7 only recovered. But this list comprised ligature of the artery for all causes, including aneurism. Thus, (1) for arrest of hæmorrhage in wounds, or in surgical operations, 11 cases, 10 deaths; (2) for aneurism, 15 cases, 10 deaths; (3) for pulsating tumour mistaken for aneurism, 4 cases, 1 recovery; (4) to obviate hæmorrhage in an operation in 1 case, and in an aneurism for anastomosis in another, making 2 cases, both of which died. The causes of death were noted in 19 cases; gangrene in only 3, exhaustion 8, hæmorrhage 6, and peritonitis 2. Five more cases may be added to Dr. Smith's table; 3 of which were fatal, and 2 successful, one by Bickersteth, of Liverpool, the other by Syme, in which he laid open the sac of an iliac aneurism, and tied the common, external, and internal, iliac arteries opening into it.

Out of the total number of cases of ligature of the common iliac, 37; 28 have died, and 9 only recovered; in 9 the peritoneum was wounded, and of these, 8 were fatal.

#### GLUTEAL, SCIATIC, AND PUDIC ARTERIES.

**ANEURISM.**—*Symptoms.*—The three chief branches of the internal iliac artery are, each, liable to spontaneous aneurism; but the sciatic and pudic arteries are very rarely affected. An aneurism of the pudic artery is preserved in the Museum of the College of Surgeons. It is about the size of a walnut, and contains laminated fibrine.

The *gluteal* artery is more liable to aneurism. Its symptoms are not peculiar; but the situation of the pulsating tumour is the posterior part of the buttock, where the gluteal artery emerges from the sacro-sciatic notch of the ilium.

As compared with pulsatile tumour of the ilium, the *diagnosis* must be guided by the distinctions already noticed. Encephaloid cancer may simulate aneurism, as happened in a case under the care of Mr. Guthrie,† who thence ligatured the common iliac artery.

*Treatment.*—*Ligature of the internal iliac.*—This operation, first performed in 1812, by Dr. Stevens, has since been repeated in 9 other cases. Of these 5 were unsuccessful, 4 successful, including one wherein the peritoneum was accidentally wounded.

**WOUNDS, and TRAUMATIC ANEURISM of the gluteal artery.**—Diffused aneurism of enormous size may follow a wound of the gluteal artery. The famous case of punctured wound of this vessel, with consequent aneurism, as related by John Bell, well illustrates the character of aneurism thus arising over the buttock. [P. p. 207.]

*Treatment.*—*Double ligature* of the vessel at the seat of injury. This operation proved thoroughly successful in the above case. The incision over the tumour was two feet in length, and eight pounds of blood were turned out of the sac; but the man ultimately "walked stoutly" and regained good health. In a case operated on by Mr. Syme,‡ the base of the

\* Amer. Journ. Med. Sciences, July, 1860.

† Med.-Chir. Trans., vol. xxviii.

‡ Obs. Clin. Surg., 1861.

tumour had attained the size of a man's head, it occupied the whole hip, and rose into a blunt cone. The result was successful.

#### COMMON FEMORAL ARTERY.

**ANEURISM.**—*Symptoms.*—The pulsating tumour of aneurism of the common femoral trunk, arises in the groin, but, it may pass partly upwards into the abdomen. Situated, otherwise, external to the pelvis, the characters of aneurism are more readily perceptible, than when the tumour is internal. Its pressure-effects are evinced by pain in the groin and down the thigh, the genito-crural and branches of the anterior crural nerves being affected; and œdema of the leg supervenes, owing to compression of the femoral and saphena veins.

The *diagnosis* must still have regard to the possibility of abscess or a cyst pulsating in connexion with the artery; and that of a pulsating tumour of the ilium. Inguinal aneurism has been punctured by mistake for abscess; and cases of pulsating tumour simulating aneurism in the groin, have occurred to both Mr. Stanley and Mr. Syme. But the pulse below an aneurism, as compared with the pulse in the other limb, is reduced; and this distinction will aid in determining the diagnosis of a pulsating tumour.

*Causes.*—A blow, strain, or other injury, has seemed to be the immediate cause of inguinal aneurism, in some cases.

*Course and Terminations.*—Restrained by the fascia lata, in the thigh, and by the pelvic fascia above, the tumour enlarges slowly, but may ultimately attain a large size. It is said never to become diffused, the fascia effectually circumscribing the aneurism; but it acquires a lobulated character under the unequal resistance thus offered to the increasing tumour.

A spontaneous cure has been known to take place in a few instances.

*Treatment.*—*Compression on the external iliac.*—This proceeding is practicable in persons not too stout, and has proved sufficiently successful to encourage a repetition. *Digital* compression was effectual in a case under Mr. Fox, of the Pennsylvania Hospital; the want of assistants, however, prevented him from thus completing the cure. Another case—in St. George's Hospital—was entirely cured by mixed digital and mechanical compression.

*Ligature of the external iliac.*—First performed by Abernethy, in 1796, this operation has since been practised in at least 100 cases, according to Norris's table. Of these, 73 were cured, and 27 died. In 92 cases, the aneurism was seated entirely in the groin; and of these, 70 were cured, and 22 died. The causes of death were partly referable to the operation; gangrene of the limb, in 8; secondary hæmorrhage, in 4; sloughing of the sac, in 3; from tetanus, 3; and from more general causes, 4. Inguinal with popliteal aneurism of the same side, co-existed in a few of these cases. This complication does not appear to lessen the efficacy of the operation. Of 4 such cases, ligature of the external iliac was successful in 3; the one dying of gangrene, but the popliteal aneurism, in that case, was about to burst at the time of operation. In 118 cases of ligature for all purposes, including aneurism, 33 died; and in 30 of these, 13 died of gangrene, 6 of secondary hæmorrhage, 3 of sloughing of the sac, 2 of tetanus, 2 of prostration, 2 of peritonitis, 1 of

diffuse inflammation, and 1 of delirium tremens. Of the remaining 2 out of 33; one death was unconnected with the operation, and in the other case the cause is not specified.

Pulsation returned in the sac in 6 of the aneurismal cases; several weeks after the operation in some cases, and followed by death in only 1 case. In 2 of the three successful cases after ligature for double aneurism on the same side, pulsation returned in the inguinal aneurism; but it ceased, after a while, in both.

*Ligature of the common iliac*, must be had recourse to, if the aneurism extends beneath Poupart's ligament into the pelvis, or partially involves the external iliac.

WOUNDS, and TRAUMATIC ANEURISM of the *Common Femoral Artery*.—*Double ligature* of the vessel at the seat of the injury, is the rule of treatment established by Guthrie's observations in this, as in all similar cases. The artery being wounded so near to Poupart's ligament, hæmorrhage will of course be more perilous, owing to the great difficulty of compressing the vessel above, in applying the ligatures.

Secondary hæmorrhage also and gangrene are both imminent subsequently.

*Amputation* is the only resource in either of these events; ligature of the external iliac has invariably failed to prevent the recurrence of secondary hæmorrhage.

ANEURISMAL VARIX, and VARICOSE ANEURISM, in the *groin*.—*Double ligature*; the tumour having been laid open, and the aperture of communication between the vessels, sought. This operative proceeding is recommended by Guthrie, as for varix and varicose aneurism occurring in other situations. But the unavoidably perilous hæmorrhage, in seeking the aperture of communication between the femoral artery and vein, will always be a most serious consideration; for it will be found impossible to safely control the hæmorrhage during the operation, by compressing the artery above.

*Ligature of the external iliac*—the alternative operation—has, on the other hand, failed entirely. In the 4 cases recorded, a fatal termination was referable to the operation; 2 dying of secondary hæmorrhage, and 2 of gangrene.

#### FEMORAL ARTERY—DEEP, AND SUPERFICIAL.

ANEURISM.—*Symptoms*.—The *deep* femoral artery is very rarely the seat of aneurism. Two cases only can I find recorded; one by Mr. Bryant, in a patient of Mr. Cock's, at Guy's Hospital; the other under the care of Dr. Garrod, at University College Hospital. In the former case, the aneurism was at the origin of the deep femoral, in the latter, lower down. The symptoms of aneurism thus situated, are necessarily somewhat obscured by the depth of the artery.

The *superficial* femoral artery is rarely the seat of aneurism, but far more frequently than the deep femoral; and as affecting this artery, it is known as Femoral Aneurism. The symptoms are more perceptible—the tumour being more superficial; particularly if situated in Scarpa's triangle, the usual situation. Aneurism springing from this—the first portion of the femoral—is unsupported by muscles immediately behind it; thus forming more readily and rapidly, it presents a pulsating tumour, having the characters of aneurism well defined. They are obscured only by the fascia lata, superficial fascia, and integument. Aneurism arising

from the second portion of the femoral—within Hunter's canal—is not only more deeply placed, but is supported by the adductor muscles, and resisted by the aponeurotic covering of the canal, and by the superimposed sartorius muscle; as well as the fascia lata, superficial fascia, and integument. The pulsating tumour, therefore, has characters less distinctly aneurismal.

The *Pressure-effects* of femoral aneurism — whichever portion of the artery be affected—will consist in the pain and œdema produced by compression of branches of the anterior crural nerve, and of the femoral and saphena veins. In Hunter's canal, the internal saphenous nerve—a branch of the anterior crural, and the femoral vein, are here peculiarly subject to pressure.

*Treatment.*—*Compression* of the *common femoral*, in the groin, should always be tried in the first instance. It has been known to succeed, even when the aneurism has burst and become diffused. If the tumour continue to increase, the establishment of a tolerably free collateral circulation will prepare the way for the next resource.

*Ligature of the common femoral*, in the groin.—The results of this operation are decidedly unfavourable. Secondary hæmorrhage is apt to follow, owing apparently to the contiguity of arterial branches—the circumflex ilii above and the deep femoral below the ligature; the free communication of which vessels is, however, requisite for the collateral circulation. Gangrene, on the other hand, is apt to ensue; in the event of the arterial trunk becoming occluded below the ligature, thus shutting off the supply of blood through the deep femoral, as well as through the superficial femoral leading to the aneurism. Of 12 cases, in which the common femoral has been ligated; secondary hæmorrhage occurred in 9, 3 of which were fatal, and 6 were saved only by ligature of the external iliac; the remaining 3 were successful.

*Ligature of the superficial femoral* will be practicable only in cases where the portion of this artery, between the sac below, and origin of the deep femoral above is of sufficient length for the application of a ligature. But this operation avoids both the sources of danger consequent on ligature of the common femoral. Ligature of the superficial femoral, in the part referred to, may be eligible for aneurism situated in the apex of Scarpa's triangle, and would certainly be appropriate for aneurism in Hunter's canal.

*WOUNDS, and TRAUMATIC ANEURISM of the Femoral Artery.*—These lesions are liable to happen by puncture with some sharp instrument, or by rupture, or penetration of the artery, with or by fracture of the femur.

Cases of this description are not very uncommon. The following instance well illustrates the symptoms. The femoral artery of a young man was wounded with a penknife. On the following day—observes John Bell—aneurism began to form, but as yet the wounded artery was not so far removed from the fascia and surface of the thigh but that pure blood found its way out through the integuments, and he lost at a few strokes of the heart no less than three pounds of blood; but on the third day, the coagula were so firm, the wounded artery so deeply buried under the coagulating blood, and the external wound so steadily compressed, that it healed. Then, the aneurism assumed its proper form of a great pulsating tumour, but circumscribed, and limited to the upper and fore part of the thigh; very little swelling of the limb had supervened after the lapse of three weeks. In another case, a man was sitting in a careless

way cutting a rag or flaw from the root of his nail, and the scissors, which were very sharp-pointed, dropping betwixt his thighs, he suddenly clapped his knees together to catch them, and struck the points into his thigh, wounding the femoral. The blood instantly spurted out, was soon stopped, and the external wound healed in a few days; then aneurism began to form.

The *Treatment* presents nothing peculiar;—*double ligature* of the artery at the seat of wound; or, if secondary hæmorrhage occurs, *ligature of the trunk* above should be had recourse to.

ANEURISMAL VARIX, and VARICOSE ANEURISM, in the thigh.—In the event of either such possible mode of communication between the femoral artery and vein, the treatment would be analogous to that for similar conditions of the common femoral artery and vein in the groin.

#### POPLITEAL ARTERY.

ANEURISM.—*Symptoms*.—Popliteal Aneurism is declared by a pulsating tumour, which forms in the popliteal space, or ham. At first, small, circumscribed and of roundish shape, soft and compressible, it subsides also by pressure on the femoral trunk. This latter symptom, as Sir A. Cooper originally observed, may be more readily perceived by looking at the tumour from the level of the limb. The pulsation, like that of other external aneurisms, can be seen and felt, as well as heard, transmitting a *bruit*. But the character of the pulsation is modified by the aspect of the artery, whence the aneurism springs. When it arises from the posterior aspect of the vessel, towards the skin, popliteal aneurism has the usual heaving and expansive character; arising from the anterior aspect towards the joint, the aneurism raises the vessel more to the surface, and the pulsation is thrilling; the beat of the vessel; also, in its course, being, perhaps, felt distinctly separate.

The *pressure-effects* of popliteal aneurism are, as with other aneurisms, pain and œdema, preceded by some stiffness of the knee-joint, and a semi-flexed position of the limb. Lameness is, indeed, often one of the earliest symptoms of the disease.

The *diagnosis* is usually unequivocal. But the pain and inability to use the joint may be mistaken for rheumatism; and other tumours in connexion with the popliteal artery, have a pulsatile character transmitted to them—*e.g.*, chronic abscess, a cyst, or solid tumour, in the popliteal space. The pulsation, however, is less expansive, the tumour incompressible, and it does not subside on pressure of the femoral trunk. These differences disappear in the event of aneurism having undergone consolidation; thus so far resembling a solid tumour. But any such independent tumour can, perhaps, be lifted off, and isolated from the artery, when its pulsatile and apparently aneurismal character ceases. The history of the case will aid in determining the diagnosis; as, for example, with regard to chronic abscess.

*Causes*.—Some strain in flexion or extension of the joint seems to be the usual mode of origin. Hence, popliteal aneurism occurs more frequently in persons accustomed to the athletic exercises of running or jumping, or who ride hard on horseback. Sailors, according to Dr. Crisp, would appear to be more subject to the disease than any other class. Men, generally, are far more liable than females. Of 155 cases, in Norris's table, 5 only were females. The *period of life* most liable is between thirty and fifty. As compared with other aneurisms, popliteal aneurism is far

less frequently associated with a diseased state of the arterial system, and with aneurism, consequently, in other parts of the body. Both popliteal arteries are affected with equal frequency, and occasionally at the same time. On the other hand, compared with other arteries, the popliteal is prone to aneurism. Thus, of 551 cases of aneurism, collected by Dr. Crisp, 137 were popliteal, and only 66 femoral.

*Course and Terminations.*—Enlarging usually with tolerable rapidity, the aspect of the artery from which the aneurism arises, regulates the rate of its progress. On the anterior aspect of the vessel, aneurism is resisted by the joint or the lower end of the femur, and increases slowly. Constant pressure on these parts is followed by synovitis or caries, and the tumour ultimately bursts into the joint. On the posterior aspect of the vessel, aneurism being supported by the hamstring muscles on either side, but restrained only by the integuments, it enlarges rapidly. Becoming diffused, it may burst upwards into the cellular texture of the thigh; or backwards, under the integuments of the popliteal space; or downwards, under the fascia overlying the posterior tibial vessels and nerve.

Rupture of the sac terminates the previous aneurismal symptoms.

*Treatment.*—*Genuflexion*, first employed successfully by Mr. Ernest Hart, should be tried, in the first instance. If bending the knee back upon the thigh stops the pulsation in the tumour, this treatment may be continued. The limb having been bandaged from the toes nearly to the knee, the roller should be turned round the thigh, flexed at an acute angle; the limb is then bent upon the pelvis, and the knee rested against a pillow. In Mr. Hart's case, the cure had made considerable advance after the first day of flexion, and was complete on the fourth day; on the seventh the patient was moving about. Other successful cases have since been recorded.

Flexion is, in fact, a mode of compression; this being the next resource when that has failed, or is ineligible owing to the large size of the aneurism.

*Compression of the femoral artery.*—Instrumental or digital compression may be readily effected; care being taken that the pressure be directed rather outwards against the femur, as the vessel winds to the inner side of the bone in its course down the thigh to become popliteal. But this kind of treatment may be unbearable. Or, the tumour still enlarging, compression will no longer prove sufficient to induce consolidation of the aneurism, and still less so, if the sac has burst, and diffused aneurism being established, gangrene is imminent.

*Ligature of the superficial femoral.*—This operative proceeding becomes necessary under the circumstances adverse to compression, or its continuance. Ligature of the superficial femoral has been attended with more successful results than that of any other main artery. The vessel is usually secured at the apex of Scarpa's triangle, just as it passes under the sartorius muscle.

In 110 cases, collected by Dr. Crisp, 12 only had a fatal issue; by secondary hæmorrhage, 4; by gangrene, 3; and the remainder dying of phlebitis, tetanus, &c. Of 33 cases operated on in London, Hutchinson shows that 10 were fatal; 5 dying from gangrene. This would seem to be the chief cause of death after ligature of the femoral for all purposes, including popliteal aneurism. Thus, of 204 such operations in Norris's tables, 50 died. Of these, the cause of death is omitted in 4; but of the remaining 46, 23 or one-half, died from gangrene, and 8 only from

hæmorrhage; 5 of phlebitis; 1 from sloughing of the sac, and the residue from accidental causes common to all operations, as tetanus, pyæmia, &c. Return of pulsation in the sac sometimes occurs, but it rarely is of much consequence. Compression of the artery above, will, mostly, control any such unfavourable tendency.

Secondary hæmorrhage may be met by ligature of the artery above—*i.e.*, the common femoral, or the external iliac; pressure with a graduated compress fixed over the bleeding aperture, or double ligature of the vessel *in situ*, will be insufficient or impracticable; and, in extreme cases, amputation is the only resource.

*Amputation of the limb.*—This operation must be resorted to in the event of *gangrene*, consequent on the aneurism, or its having become diffused, or after ligature of the superficial femoral. Persistent secondary hæmorrhage will also render amputation unavoidable. Limited gangrene may allow the preservation of the limb.

Amputation has proved tolerably successful in its results, more so than ligature of the femoral, taking either operation in all cases indiscriminately. Of 50 cases of ligature collected by Mr. Hutchinson from the practice of the metropolitan hospitals, 16 died, or nearly one-third; whereas, amputation of the thigh—in all the cases collected by Mr. Bryant from Guy's Hospital, and by Mr. Holmes from St. George's Hospital—shows a mortality considerably below one-third.

DOUBLE POPLITEAL ANEURISM.—*Compression* seems to Mr. Erichsen specially appropriate in double popliteal aneurism, as thus to avoid that disturbance of the balance of the circulation which is certain to ensue when one vessel is ligatured, and which may act injuriously upon the opposite aneurism.

*Ligature* of the artery has occasionally been practised with advantage on both sides; either simultaneously, or, with more safety, consecutively.

WOUNDS, and TRAUMATIC ANEURISM of the Popliteal Artery.—Should either of these lesions occur, they would present nothing peculiar as to symptoms or treatment.

Rupture of the artery, subcutaneously, has been met with. In one case, *double ligature* of the vessel was performed by Mr. Poland,\* with an unsuccessful result, gangrene having supervened on the third day, followed by amputation and death. But no difficulty was experienced in the operation. The only two other cases wherein double ligature of the popliteal has been attempted, failed in the operation. Ligature of the femoral has been tried in two cases, both of which terminated fatally by gangrene. In one case, accompanied with rupture of the popliteal vein, which occurred in my own practice, gangrene ensued, for which *amputation* was performed above the knee, with, however, a fatal result. (Page 258.)

#### TIBIAL ARTERIES—ANTERIOR AND POSTERIOR.

ANEURISM.—*Symptoms.*—Very rarely, spontaneous aneurism occurs below the knee, in connexion with either of the tibial arteries. A small aneurism of the posterior tibial is preserved as a preparation in the Museum of St. George's Hospital. The symptoms will probably be obscure, owing to the small size of any such aneurism, and its depth from the surface; especially as connected with the posterior tibial, throughout the greater portion of the course of that vessel.

\* Guy's Hosp. Reports, 3rd series, vol. vi.

The *Treatment* must be conducted on the same principles as for aneurism in other situations; *compression* above the tumour, when practicable; or, that having failed, *ligature* of the *femoral* should be duly considered, with reference to the probability of curing the aneurism and also the consequent perils of this operation.

WOUNDS, and TRAUMATIC ANEURISM.—*Double ligature* of the vessel, at the seat of wound, or resulting aneurism, is unquestionably, as in all similar cases, the appropriate rule of treatment. But this operative procedure may be rendered impracticable by the depth of the vessel, especially in a muscular limb, and increased by the infiltration of blood. Under these circumstances, other procedures have, occasionally, been resorted to; and, in the event of secondary hæmorrhage, they must be taken into consideration.

*Ligature of the popliteal or femoral artery*, has thus proved successful in arresting hæmorrhage. Wound of the posterior tibial, with secondary hæmorrhage, warranted ligature of the popliteal artery, in a case under the care of Samuel Cooper; and diffused traumatic aneurism of the same vessel, seemed to justify ligature of the femoral, in a case under Dupuytren.

*Amputation* should always be the last resource.

ANEURISMAL VARIX, and VARICOSE ANEURISM.—The latter condition has occurred in the posterior tibial artery and one of the *venæ comites*, just above the internal annular ligament at the ankle-joint. The two vessels communicated through a small circumscribed aneurism intervening between them. No history, I believe, could be ascertained; this varicose aneurism having been discovered by Mr. Cadge in the dissecting room of University College, when he was Demonstrator of Anatomy in that Institution; and I well remember he showed me the specimen, which is, I believe, unique.

## CHAPTER XXV.

### LIGATURE OF ARTERIES.

OPERATIONS for the Ligature of Arteries are more conveniently and instructively described, consecutively; rather than severally, in connexion with the various Aneurisms to which these Operations pertain.

Thus viewing the Arterial System, Surgically, the similarity of anatomical relations in contiguous portions of the same artery, will save much unnecessary repetition, which would otherwise be unavoidable, in describing the operations for their ligature.

Certain *general directions* are applicable to the ligature of all arteries; and they relate either to the operation as performed on an artery in its continuity, or at the seat of a wound involving an artery.

LIGATURE OF AN ARTERY IN ITS CONTINUITY.—This operation consists in dividing the textures down to the artery, and then applying a ligature around the vessel. A muscle or tendon, or perhaps a bone, is observed as the recognised guide for the *incision*. Thus, the inner border of the biceps muscle guides to the brachial artery, the tendon of the supinator longus leads to the radial, and the upper margin of the clavicle, in its outer third, is the line of incision leading to the subclavian in the third

part of its course. In the absence of any such anatomical "directing line," a line can, mostly, be drawn corresponding to the course of the artery. For example, midway between the anterior superior spinous process of the ilium and symphysis of the pubes, a line commencing, and terminating on the inner side of the patella, nearly indicates the course of the femoral artery.

The *incision* may be made in the line thus indicated naturally or artificially, or obliquely across that line; the latter direction guiding to the artery which it bisects in some point of its course, and leading more clearly to the parts adjacent on either side of the vessel. The *length* of incision should be proportionate to the depth of the artery, which has to be reached, thence varying from one to three inches or more; but generally the skin alone should be first divided, the integument being gently stretched, without displacement, by the fingers of the left hand. Then, the subjacent fascia, its superficial and deep layers, and muscle in some cases, must be carefully divided, in succession; any known veins or arterial branches being avoided, if possible, or hæmorrhage from them commanded by pressure, torsion or ligature. Adjoining the artery, a nerve may be found, lying by the side of the vessel, but outside its sheath—*e.g.*, the ulnar nerve in collateral relation to the ulnar artery; or several nerves may surround the vessel, as the brachial plexus in relation to the brachial artery. Any such superficial vessels, the border of a muscle or tendon, and nerves, are conveniently drawn to one side and protected, and the wound made more open, by curved metallic spatulæ; wherewith retraction can be gently maintained by an assistant, as the textures are successively divided; and also during the passage of the ligature-needle around the artery.

The *sheath* of the artery having been reached—as denoted by its dense cellular character, and the pulsation of the enclosed vessel, immediately beneath the finger—that structure should be slightly raised with the forceps, into a small cone off the artery, and the knife being laid flat under the pinch of the forceps, a small aperture is cut in this portion of the sheath. The artery thus exposed, through the aperture, will be recognised by its whitish-yellow or fawn colour. Enclosed within the sheath, by the side of the artery, lies the small companion vein, or two such veins, *venæ comites*, one on either side, in relation to a second-sized artery. It, or they, have a dark-blue colour, contrasting with the colour of the artery; but any enclosed vein may be only partially visible through the small aperture in the sheath. A nerve also is sometimes enclosed, as the pneumogastric within the sheath of the carotid, but it has less immediate relation to the artery; while external to the sheath, the collateral nerve or nerves already referred to will be seen, in immediate relation to the artery.

An *aneurism-needle*, armed with a waxed silk ligature, is introduced (Fig. 64) through the aperture in the sheath, between the vein and artery, and turned round the latter; their cellular connexion having, previously, been gently separated, if necessary,

FIG. 64.

by scratching with the point of the needle. The *ligature* is drawn out from the eye of the needle, and the needle itself withdrawn; leaving one end of the thread on either side of the artery.

FIG. 65.

Special care should be observed not to slide the ligature up and down the artery, nor to lift up the vessel much from its bed; whereby, in either way, the nutrient *vasa vasorum* would be cut or torn off, endangering sloughing of the vessel and secondary hæmorrhage. The ligature should be tied transversely round the artery, as an oblique direction of the noose would be liable to loosen; the ends of the thread must be drawn moderately tight, so as to divide the two inner coats of the vessel, and then the thread tied again forming a reef-knot (Fig. 65).

It must be observed in these proceedings, that the *vein* be not wounded or transixed, nor any adjacent *nerve* included in the ligature with the artery. But care should also be taken, not to ligature any extraneous structure *instead* of the vessel; as a nerve, or portion of the sheath. The finger placed on the *distal* side of the artery will at once discover whether pulsation is stopped, and the vessel secured. One end of the ligature is then to be snipped off close to the knot on the vessel, and the other end left hanging out of the wound, guarded by a small strip of adhesive plaster; and lastly, a piece of wet lint is placed over the incision.

**LIGATURE OF AN ARTERY AT THE SEAT OF A WOUND, INVOLVING THE VESSEL.**—The wound is here used as the incision, leading down to the artery. It may require to be enlarged, as in the case of a punctured or other narrow wound; and much difficulty may be experienced in finding the vessel, owing to the infiltration of surrounding textures with blood. The artery may be found *punctured*, or completely *divided*. In either case, the rule of treatment for securing it and arresting hæmorrhage, is the same.

A ligature must be applied on either side of the aperture, or to either cut extremity; this *double ligature* being necessary to control the hæmorrhage from the distal, as well as the cardiac end of the artery—which would otherwise continue to bleed by the anastomotic supply of blood from above the upper ligature.

Puncture, or division, of an arterial branch *close* to the *trunk* whence it springs, is equivalent to an aperture in that vessel of equal size to the branch or the puncture in it. The same treatment therefore will be requisite; ligature of the trunk above and below the branch.

Ligature of an artery, on the *surface* of a wound—*e.g.*, a stump after amputation—has been described in connexion with INCISED WOUNDS.

The Ligature of Arteries will now be described severally, and in consecutive order from the commencement of the Arterial System to the Extremities; associating with each such Operation a preparatory summary of the Surgical Anatomy of the Artery.

**LIGATURE OF THE INNOMINATE OR BRACHIO-CEPHALIC ARTERY.**—*Surgical Anatomy.*—This artery *arises* from the commencement of the transverse portion of the arch of the aorta, and ascends *obliquely* to the right, as high as the *sterno-clavicular* articulation; where it divides into right subclavian and right carotid arteries. Its *length* is, usually, an inch and a half to two inches. Situated within the thorax, behind the first piece of the sternum; the vessel is immediately *overlaid*—from below upwards—

by the left innominate vein, crossing its root, the sterno-hyoid and sterno-thyroid muscles; and above it passes between and behind the cellular interval of the sternal and clavicular portions of the sterno-mastoid muscle. *Posterior* to the artery, is the trachea, on which it lies, obliquely; on its *left* side, is the left carotid artery, but as the innominate ascends to the right, a considerable interval separates the two vessels, in which appears the trachea, with some remains of the thymus gland; on the *right* side is the right innominate vein. Nearly parallel with the artery, and along the outer side of the vein is the phrenic nerve and the pleura. The pneumogastric nerve, entering the thorax, between the subclavian artery and innominate vein, gives off its recurrent branch around that artery, and then dips backwards by the side of the trachea, to lie in the interval between that tube and the œsophagus. This nerve, therefore, has no immediate relation to the innominate artery, otherwise than just as the nerve enters the thorax behind the vein and to the right of the artery, here lying on the right side of the trachea.

*Operation.*—The innominate may be reached from *above* the sternum. The patient being placed in the recumbent position, and the head thrown well back, exposing the root of the neck; an incision is commenced in the epi-sternal notch near the right sterno-clavicular articulation, and carried upwards to the left, for about three inches, near the inner side of the left sterno-mastoid muscle. (Fig. 66.) A second incision, if necessary, may be made from over the sternal origin of the right sterno-

FIG. 66.

mastoid muscle, meeting the lower end of the first incision at nearly a right angle. The skin and superficial fascia are thus divided, and if a flap of integument has been formed by the second incision, it is turned up; the deep fascia is cautiously divided, and the finger passed down the trachea to the artery; or, if a flap be made, the sternal origin of the right sterno-mastoid muscle and a few fibres of the sterno-thyroid and hyoid muscles, may also be divided; and the root of the carotid thus exposed, is followed down to the innominate. A round curved aneurism-

needle, armed with a ligature, is then passed around the vessel, and the ligature secured, with all the skill the Surgeon can command. A needle having a point which can be detached, when felt under the vessel, may help to facilitate this critical part of the operation.

The innominate has been reached *anteriorly*, by removing a piece of the sternum and sternal end of the clavicle. This was done by Cooper of San Francisco,\* in a case where the upper end of the innominate artery itself was diseased, and the aneurism affected the *root* of the subclavian and carotid arteries. But it is only for the cure of aneurisms in that situation, that ligature of the innominate would ever be contemplated; and disease of any portion of this vessel—the seat of operation—would be a positively forbidding condition. In the case referred to, and in all instances of the less formidable operation, above the sternum, the result has been fatal.

LIGATURE OF THE COMMON CAROTID.—*Surgical Anatomy*.—The right and left common carotid arteries differ only in part of their course; that portion of the latter vessel which extends from its origin on the arch of the aorta to the left sterno-clavicular articulation, or the thoracic portion of the left common carotid. But this part of the left carotid artery is never selected for ligature.

The common carotid on the *right* side, and the cervical portion of the *left* common carotid, extends from behind the *sterno-clavicular* articulation to the upper border of the *thyroid cartilage*; where it divides into *external* and *internal* carotid arteries. The artery has an *oblique direction* upwards and outwards; corresponding to a line drawn from the sterno-clavicular articulation to a point midway between the angle of the jaw and the mastoid process of the temporal bone. It seems to have an inclination backwards, superiorly, owing to the projection forward of the larynx, in that situation. The artery with the internal jugular vein and pneumogastric nerve, are enclosed in a common membranous *sheath*, continuous with the deep cervical fascia. The vein, within this sheath, is situated along the outside of the artery, a thin cellular partition only intervening; the nerve lies behind and between the two vessels. Thus so far isolated, the artery is deeply placed at the lower part of the neck, and more superficial above. *Below*, the sheath is *covered* by the sterno-mastoid, sterno-hyoid, and sterno-thyroid muscles, and crossed by the omo-hyoid muscle obliquely upwards just below the cricoid cartilage. Superficial to these muscles, is the skin and superficial fascia, and a small portion of the platysma myoides as it passes upwards from the clavicle to the lower jaw; the deep cervical fascia ensheathing the muscles and passing down behind them, continuous with the sheath of the vessels, into the thorax. Crossing the sheath is the middle thyroid vein. *Above* the cricoid cartilage, the artery is covered only by the skin and superficial fascia, platysma and deep fascia. Crossing the sheath here are the superior thyroid veins, which sometimes form a plexus in this situation. The descendens noni, a branch of the hypoglossal nerve, lies on the sheath of the vessels from above downwards, inclining from the outer to the inner side. Occasionally, this nerve runs within the sheath, and between the artery and vein. *Posteriorly*, the artery, throughout its course is supported by the transverse processes of the cervical vertebræ; a thin stratum of muscle intervening, consisting of the longus colli and scalenus anticus. The sympathetic and recurrent laryngeal nerves, and

\* Amer. Journ. Med. Sciences, Oct. 1859.

inferior thyroid artery, are also in relation with the posterior aspect of the artery. On the *inner* side of the artery; below, lie the trachea with the thyroid body, which often overlays the vessel; above, the larynx and the pharynx. On the *outer* side is a chain of lymphatic glands, between the sheath and the inner border of the sterno-mastoid muscle, which corresponds to the artery in the upper part of its course. Within the *sheath*, the large internal jugular vein is in immediate relation, on the outer side of the vessel.

*Operation.*—The patient should be placed in the recumbent position, with the head thrown back, and the face turned a little from the side of operation; thus exposing the side of the neck. The *apex* of the carotid triangle, where the omo-hyoid muscle crosses the artery, is selected, if possible, as the seat of ligature; the inner margin of the sterno-mastoid muscle being the guide to the artery. An incision, from two to three

FIG. 67.

inches long, on the inner edge of this muscle, should be so placed that the centre about corresponds to the lower border of the cricoid cartilage. (Fig. 67.) The skin, superficial fascia, and platysma, are thus divided. Turning the head a little so as to relax the sterno-mastoid, the deep fascia must be cautiously divided, and the sheath of the vessels exposed, with the omo-hyoid crossing it. The thyroid veins, turgid with blood, passing across the sheath of the vessels, and the descendens noni lying in front of the sheath, are drawn to either side of the wound with spatulæ by an assistant. The operator introducing his

finger into the wound, feels the artery beating between the trachea and sterno-mastoid muscle. The sheath is now opened in the usual way, by a pinch up with the forceps and lateral application of the knife; the aneurism-needle should be gently insinuated, on the outer side of the artery, between it and the vein, taking care not to include the pneumogastric nerve in dipping the needle round the vessel; the ligature is then drawn through and secured, without disturbing the vessel.

The operation *lower* down in the neck, necessitates the division of the sternal portion of the sterno-mastoid muscle. The sterno-hyoid and thyroid muscles may be drawn to the outer side. Any thyroid veins and the internal jugular, which, on the left side, inclines to the front of the artery, will also thus be avoided; and the ligature is then passed as above.

LIGATURE OF THE EXTERNAL, AND INTERNAL, CAROTID.—*Surgical Anatomy.*—(1) The *external* carotid arising from the *bifurcation* of the common carotid, opposite the upper border of the thyroid cartilage, extends upwards to the neck of the *condyle* of the lower jaw, between it and the

mastoid process; there dividing into two branches, the temporal and internal maxillary arteries. In this course, it lies, at first, on the *inner* side of the internal carotid, and then superficial to that vessel. But its *depth* varies below and above the *digastric muscle*, or a line drawn from the mastoid process to the hyoid bone.

Below that muscle or line, the external carotid is *covered* only by the skin and superficial fascia, the platysma, and deep fascia; then, passing beneath the digastric and stylo-hyoid muscles and hypoglossal nerve, which cross obliquely, the artery enters the substance of the parotid gland, beneath the fascial nerve and the external jugular vein. Here then the artery is deepest, and inaccessible. *Posteriorly*, the artery rests on the pharynx, and the superior laryngeal nerve; and above the angle of the jaw, on the styloid process and glosso-pharyngeal nerve, which separate it from the internal carotid. To the *inner* side, is the pharynx, and above, the ramus of the jaw and stylo-maxillary ligament. On the *outer* side, the internal carotid lies parallel with the external carotid, at the origin of the two vessels; but this relationship is soon lost, as the external vessel becomes more superficial in passing to its destination. More externally, the inner edge of the sterno-mastoid muscle corresponds to the artery.

(2) The *internal carotid*, arising from the *bifurcation* of the common trunk, extends upwards to the *carotid foramen* in the temporal bone; and there, passing through the carotid canal in that bone, it enters the *cranium*. The cervical portion, limited by the carotid foramen, varies in *depth*—like the external carotid—with its relation to the *digastric muscle*. Below that muscle, the artery is *covered* only by the skin and superficial fascia, platysma, and deep fascia; then passing beneath the external carotid, separated by the styloid process and glosso-pharyngeal nerve—at the angle of the jaw—it lies under the deep surface of the parotid gland, until it enters the carotid foramen. *Posteriorly*, the artery rests on the transverse processes of the upper cervical vertebrae; the rectus anticus major muscle, sympathetic and superior laryngeal nerves, intervening. *Internally*, the pharynx and tonsil are in contact; and the ascending pharyngeal artery runs up, on the pharynx, between the vessel and the external carotid. *Externally*, the internal jugular vein runs side by side with the artery, and the pneumogastric nerve behind and between the two; these structures having the same relation as to the common carotid, of which the internal carotid seems to be the continuation. The hypoglossal nerve comes forward between the vein and artery, and passes inwards over the latter to gain the lower border of the digastric muscle, over the external carotid; thus crossing both arteries superficially. The inner margin of the sterno-mastoid muscle corresponds to the artery, externally.

*Operation*.—The neck must be well exposed as for the ligature of the common carotid. Guided by the *sterno-mastoid*, an incision along its inner margin—from the angle of the jaw to just above the level of the thyroid cartilage—will lead down to the *internal carotid*; and a little more internally, to the *external carotid*. The digastric muscle and hypoglossal nerve crossing the latter near the upper angle of the incision, identify this artery. A small aperture is made in the sheath of the vessel to be ligatured, and an aneurism-needle passed betwixt it and the vein; as in the operation on the common carotid.

LIGATURE OF THE LINGUAL ARTERY.—*Surgical Anatomy*.—*Arising* from the inner aspect of the external carotid, between the superior thyroid and

fascial branches; the lingual passes slightly upwards and inwards to the great cornu of the hyoid bone; and above it, continues forwards beneath the hyoglossus muscle, at the anterior border of which it gives a branch—sublingual, to the sublingual gland; and then *terminates* as the *ranine* branch, along the outer side of the genio-hyoglossus, extending to the tip of the tongue. Having this somewhat tortuous *direction*, the artery is comparatively superficial below and above the great cornu of the hyoid bone, in this part of its course being *covered* only by the skin, platysma, and fascia; but it is then crossed by the digastric and stylohyoid muscles passing to the body of the hyoid bone, and the artery enters deeply beneath the muscles; it is concealed entirely by the mylohyoid, as well as overlaid in part by the hyoglossus. *Resting* on the middle constrictor of the pharynx, the vessel afterwards lies on the geniohyoglossus muscle, *beneath* the hyoglossus, and in its course as the ranine artery under the tongue. The hypoglossal nerve, winding round the lower border of the posterior belly of the digastric muscle, passes upwards beneath it, and approaching the posterior margin of the hyoglossus muscle, the nerve is there situated above the lingual artery; continued *over* that muscle to its anterior margin, the nerve has become inferior, and there sinks into the fibres of the genio-hyoglossus muscle, the artery-*ranine* lying on the muscle.

*Operation.*—The lingual artery can be more readily reached, if necessary, in the *superficial* part of its course; and the upper border of the great cornu of the hyoid bone will guide to the artery in an accessible situation. Having placed the head so as to expose the digastric triangle under the jaw; an oblique incision should be made from below the symphysis of the jaw, over the cornu of the hyoid bone, to the border of the sterno-mastoid. (Fig. 69, *f*.) Dividing the skin, platysma, and fascia; any veins in the way and the tendon of the digastric may be drawn upwards, and the artery sought, above the cornu and below the nerve. Care must be taken not to penetrate the pharynx—superior constrictor, on which the vessel here rests; and such caution is especially necessary, as the thin pharyngeal bag rises and subsides under the knife. Application of the ligature presents no special difficulty.

LIGATURE OF THE SUBCLAVIAN.—*Surgical Anatomy.*—The right and left subclavian arteries differ only in part of their course; that portion of the latter vessel which extends from the arch of the aorta to the inner margin of the first rib at the root of the neck, or the *thoracic* portion of the left subclavian. But this part of the left subclavian artery is never selected for ligature.

The subclavian on the *right* side extends from behind the *sterno-clavicular* articulation, and the *cervical* portion of the *left* subclavian from the *first rib*, outwards to the *lower margin* of the first rib; *arching*, in its course, over the apex of the lung and pleura, and passing between the scaleni muscles.

Either artery, in this course, may be divided into *three portions*, for the convenience of description, surgically as well as anatomically. The *first* portion, extends from the sterno-clavicular articulation—or first rib, on the left side—to the inner border of the anterior scalenus; the *second* portion, beneath the scalenus; and the *third*, from the outer border of that muscle to the lower margin of the first rib. The anterior scalenus muscle is thus the boundary between the inner and outer portions of the subclavian artery, and of the middle portion beneath that muscle.

(1) *Internal* to the anterior scalenus, the artery ascends slightly outwards, and is deeply placed. *Covered* by the skin, platysma, and fascia, it is also concealed by the clavicular origin of the sterno-mastoid and by the sterno-hyoid and sterno-thyroid muscles. Deeper still, and immediately in front of the artery crossing it from above downwards, are the pneumogastric nerve and the internal jugular vein; the latter having inclined outwards from the common carotid in the lower part of the neck, leaves a triangular interval between these two vessels. Along the base of this interval lies the subclavian artery; the pneumogastric descends vertically over it, and sends off its recurrent laryngeal branch, which hooks up behind the vessel. *Posteriorly*, the artery is opposite to the transverse processes of the vertebræ, and longus colli muscle, but separated by a cellular interval; in which the trunk of the sympathetic and recurrent laryngeal nerve are in more immediate relation, the latter having hooked round the artery. *Inferiorly*, the artery lies on the pleura; and lower down, the corresponding portion of the subclavian vein runs transversely inwards to join the internal jugular, in forming the innominate vein, behind the sterno-clavicular articulation.

Three *branches* arise from the subclavian, in this part of its course; the vertebral, ascending to the head through the foramina in the transverse processes of the cervical vertebræ; the internal mammary, descending to the chest; and the thyroid axis, a short thick trunk arising from the front of the artery, and dividing into the inferior thyroid, the supra-scapular, and transverse cervical branches.

The first part of the *left* subclavian is more vertical, the internal jugular and pneumogastric incline inwards over the common carotid, the recurrent branch is given off round the arch of the aorta; and thus the artery may be somewhat more free than on the right side.

(2) *Beneath* the scalenus, the subclavian reaches its highest point above the clavicle, is transverse and curved in direction, and placed less deeply than in the first part of its course. *Covered* by the skin, platysma, and fascia, it has also in front of it, the clavicular origin of the sterno-mastoid, and the anterior scalenus muscles; the latter being attached by a flat narrow tendon to the inner border and upper surface of the first rib. Between the two muscles, the phrenic nerve descends obliquely inwards, lying on the scalenus. *Posteriorly*, the artery rests on the posterior scalenus muscle; thus passing between the scaleni. *Above* the artery, in this interval, are the large trunks of the lower cervical nerves which form the brachial plexus. *Below*, the artery curves over the apex of the lung and pleura. The subclavian vein runs transversely inwards, below the level of the artery; the anterior scalenus muscle intervening between the two vessels.

One *branch* only arises from this part of the subclavian; namely, the superior intercostal artery from its posterior aspect, which turns downwards over the neck of the first rib to supply the first two intercostal spaces. On the left side, this branch springs, commonly, from the first portion of the subclavian; thus making four, or all the branches of this artery, to arise from that part of the vessel.

(3) *Beyond* the scalenus, the subclavian descends to the *lower margin* of the first rib, and is more superficial than in either of the previous portions of its course. It is situated in the lower or clavicular part of the posterior triangular space of the side of the neck; behind and partly below the middle third of the clavicle. But the depth of the artery

below this bone will vary with the elevation of the shoulder, whereby it may sink altogether below that level.

It lies in a small triangular space : bounded, internally by the outer border of the sterno-mastoid concealing the anterior scalenus ; superiorly, by the omo-hyoid muscle passing slantingly upwards and inwards to the sterno-mastoid and then beneath it ; and inferiorly, by the clavicle. This small space is commonly not more than one inch and a half in extent, from the sterno-mastoid outwards, and about the same from above downwards along that muscle. But these dimensions will vary with the length of the clavicular origin of the sterno-mastoid, and the clavicular attachment of the trapezius. Usually attached, respectively, to the inner and outer third of the clavicle ; the muscles in some persons may nearly meet along the whole length of this bone. Then again, the height to which the omo-hyoid rises about the clavicle considerably affects the vertical length of the space. Its *depth* varies naturally with the thickness of the neck, and is altered by the position of the shoulder.

This portion of the subclavian is *covered* only by the skin, platysma, and fascia, with some of the superficial descending branches of the cervical plexus ; but below, the artery is under cover of the clavicle and crossed, beneath this bone, by the supra-scapular branch from the thyroid axis. The transverse-cervical branch traverses the upper angle, at the junction of the omo-hyoid and sterno-mastoid muscles. Here also, the external jugular vein coming downwards over the last-named muscle, enters the space to open into the subclavian vein. The artery *rests* on the pleura and upper surface of the first rib ; on which, between the vessel and the tendon of the scalenus, a *tubercle* may be felt—the guide to the artery. *Above*, is the brachial plexus, consisting of three nervous cords, supported by the posterior scalenus muscle ; *below*, lies the subclavian vein.

No branch arises from this, the third portion of the artery.

*Operation.*—*Internal to the scalenus.*—A transverse incision over the clavicular origin of the sterno-mastoid, leads down to the vessel in this part of its course. (Fig. 69, c.) But a vertical incision also along the inner border of the muscle may be added, if necessary, for space ; and the V-shaped flap of integument raised, with the platysma and fascia. The clavicular portion of the muscle and the sterno-hyoid and sterno-thyroid muscles beneath, are then to be divided transversely, just above the clavicle, and the vessel exposed. The internal jugular vein may be drawn outwards and guarded with a spatula, and the pneumogastric nerve being avoided, the aneurism-needle armed with a ligature should be passed around the artery from below upwards.

*Beneath the scalenus.*—A V-shaped incision should be made, but with the angle looking inwards. Thus, a transverse incision over the clavicular origin of the sterno-mastoid, from two to three inches in length, is met by a vertical incision about two inches long, rather external to the outer border of the sterno-mastoid ; and the flap of skin, platysma, and fascia, is raised upwards and inwards. The external jugular vein may be conveniently drawn outwards. The clavicular portion of the sterno-mastoid must then be divided inwards as far as may be necessary to expose the anterior scalenus clearly. The phrenic nerve lying on that muscle, and the internal jugular vein along its inner border, are to be drawn inwards, and guarded with a spatula. Partially dividing the muscle with caution, from without inwards, the artery comes into view. The aneurism-needle should be passed from below upwards.

*Beyond the scalenus.*—The shoulder being depressed as low as possible, and the skin of the neck drawn down over the clavicle, a transverse incision is made along the clavicle, extending from the border of the sterno-mastoid outwards to the trapezius muscle, and in depth down to the bone. (Fig. 68.) The skin, platysma, and fascia are thus divided. On allowing the integuments to resume their place, the incision will rise to just above and parallel to the clavicle. If there be reason, as already explained, to suppose that the artery lies deeply, a vertical incision may be added, as in Fig., or along the outer border of the sterno-mastoid muscle, and meeting the transverse one below at a right angle. The sterno-mastoid or trapezius, approaching each other along the clavicle in some cases, either or both these muscles may be here divided sufficiently to reach the artery on the first rib. The external jugular vein should be drawn inwards, and the deep cervical fascia cautiously divided to expose the artery. The supra-scapular artery running outwards nearly under the

Fig. 68.

clavicle, must be drawn down, and the omo-hyoid muscle upwards and outwards, thus also guarding the transverse cervical artery at about the junction of the omo-hyoid and sterno-mastoid muscles—the upper angle of the triangular space in which the subclavian lies. This vessel, fawn-coloured, will now be fairly seen; with the three white cords of the brachial plexus above, and the large, turgid, blue subclavian vein below. On passing the finger down the anterior scalenus, the *tubercle* on the upper surface of the rib can be felt, and thus the situation of the artery, ascertained; lying, as it does, on the outer side of the tubercle. Avoiding the sub-

clavian vein, the aneurism-needle should be insinuated between it and the artery, but care must also be taken not to include the lowest of the three nervous cords, as the point of the needle emerges on the opposite side. The depth and narrowness of the space, in some cases, may render this proceeding perplexing, and considerable difficulty may be experienced in fixing the ligature, it being perhaps impossible to reach the vessel with both forefingers. As a substitute, Liston recommended a *serre naud* to be used—a strong wire, perforated or notched at one end. One only, or two, may be employed, or a double one, according to the judgment of the Surgeon. Of course, the effect on the pulsation below should be ascertained before tightening the ligature. A suture or two having been inserted to bring the edges of the wound together, the limb must be elevated and wrapped in cotton wool to maintain the circulation, as after the ligature of any other main artery.

**LIGATURE OF THE AXILLARY ARTERY.**—*Surgical Anatomy.*—This vessel—the continuation of the subclavian—extends from the *lower border* of the first rib, through the axilla, to the *lower border* of the conjoined

tendon of the latissimus dorsi and teres major muscles, at its insertion into the inner edge of the bicipital groove of the humerus. *Curved* in its direction, the convexity of the curve looks upwards as the arm lies by the side of the body; but the artery becomes straight when the limb is raised to a right angle with the chest.

The axillary artery may be divided, for the convenience of description, into *three parts*; the *first* above, the *second* beneath, and the *third* below, the small pectoral muscle. The two first portions are more deeply placed than the third portion of this vessel, which becomes superficial below the great pectoral muscle.

*Posteriorly*, the artery lies *above*, on the first intercostal space and first digitation of the serratus magnus muscle, also the nerve to that muscle—the posterior thoracic or external respiratory of Bell—which entering the apex of the axilla from the posterior scalenus, crosses underneath the artery. *Beneath* the small pectoral, the artery is opposite to, but not in contact with, the upper portion of the subscapularis muscle; *below* that boundary, the vessel lies on the lower part of the subscapularis, and then on the tendons of the latissimus and teres major muscles. *Anteriorly*, the artery is covered throughout its course by the skin and fascia; and above, by the clavicular portion of the great pectoral muscle, under which is a prolongation from the costo-coracoid membrane to the sheath of the vessels. The cephalic vein, lying in the interval between the deltoid and great pectoral muscles in front of the shoulder, sinks near the clavicle under the latter muscle, and crosses the axillary artery to open into the axillary vein. It thus penetrates the costo-coracoid membrane, which is also perforated by the acromial thoracic artery—a short trunk from the front of the axillary, and by the outer of the two anterior thoracic nerves—a small branch from the outer cord of the plexus, and which crosses inwards over the axillary artery to enter the under surface of the great pectoral muscle. The inner anterior thoracic nerve—a small branch from the inner cord—turns upwards between the artery and vein to enter the under surface of the small pectoral muscle.

Beneath the small pectoral, the artery is covered by that muscle and the superimposed part of the pectoralis major. The portion of artery below the small pectoral is overlaid by the lower border of the great pectoral, and then only by the skin and fascia, superficial and deep. On the outer side, the coraco-brachialis muscle lies along this portion of the artery, thus completing its muscular relations.

Enclosed in a common *sheath* with the artery are—the axillary vein to its inner side, and the two cords of the brachial plexus, lying to the outer side of the artery *above* the small pectoral. *Beneath* that muscle they assume a new arrangement. The lowest, or inner nervous cord, passes to the inner side of the artery, separating it from the vein; and either cord furnishes a fasciculus, which uniting, form a third cord *behind* the vessel. Near the lower border of the small pectoral, a fasciculus from either primitive cord, *outer* and *inner*, form the median nerve which passes to the outer side of the artery, the fasciculus from the inner cord having crossed *over* the vessel to join that from the outer cord. Thus the artery is surrounded with nerves in this the second portion of its course, or beneath the small pectoral muscle. Below this muscle, the vessel is even more entirely surrounded with nerves. On the outer side lie the external cutaneous as well as the larger-sized median nerve, both derived from the outer cord; on the inner side, between the artery and

vein are the ulnar, internal cutaneous, and nerve of Wrisberg, all derived from the inner cord; and behind the artery are the musculo-spiral and circumflex nerves, both derived from the posterior cord. Three subscapular nerves are also derived from the posterior cord, but these muscular branches have no immediate relation to the artery.

Six *branches* are given off by the axillary artery—the superior thoracic, opposite the first intercostal space; the acromial thoracic to the pectoral and deltoid muscles; the alar thoracic, an inconstant branch to the axillary glands; the long thoracic under the lower border of the great pectoral muscle to about the sixth intercostal space; the subscapular branch along the lower border of the muscle so named; and the circumflex branches anterior and posterior, the latter being the larger, encircling the neck of the humerus.

*Operation.*—Above the small pectoral muscle.—An incision is made just under the clavicle, extending from near its sternal end to the interval

FIG. 69.

between the pectoral and deltoid muscles, on the inner side of the acromion. (Fig. 69, *a*.) The pectoral muscle is next divided to this extent, and the costo-coracoid sheath cautiously opened; then the cephalic vein being drawn to the outer side, thus also protecting the cords of the brachial plexus more deeply placed, the axillary vein is drawn towards the chest, and the ligature-needle passed under the artery from within outwards. If the trunk of the acromial thoracic artery be wounded, it will bleed almost as profusely as an aperture in the axillary trunk; and the

inclusion of either anterior thoracic nerve should be avoided in passing the ligature.

*Beneath* the small pectoral muscle, the artery should not be selected for operation, owing to its greater depth in that part of its course, and more intimate relation to the cords of the brachial plexus.

*Below* the small pectoral, the artery is most superficial and accessible, particularly beyond the great pectoral muscle. Abducting the arm and bending the forearm, will bring the vessel even more to the surface, and also relax the nervous cords surrounding it. An incision about three inches long may be made from the lower border of the great pectoral muscle, downwards over the course of the artery, along the border of the coraco-brachialis muscle; and the skin and fascia divided. The deep or aponeurotic fascia must then be divided. By drawing the median nerve to the outside, and the vein to the inside of the wound, the artery can readily be discovered, and separated so as to pass the ligature-needle without including either of the adjoining nerves which lie around the vessel.

*LIGATURE OF THE BRACHIAL ARTERY.*—*Surgical Anatomy.*—In continuation of the axillary, the brachial artery commences at the *lower border* of the tendon of the latissimus and teres major muscles, and

terminates just below the bend of the elbow, opposite the *neck* of the radius; where it divides into the *radial* and *ulnar* branches. In *direction*, this artery winds round the humerus, from above at its internal aspect, to below in front of that bone and the elbow-joint. Throughout its extent, the vessel is superficial; except at the elbow, where it sinks into the flexure of the joint.

*Covered* throughout its course, by the skin, superficial and deep fascia; at the elbow, the brachial artery is also overlaid by a prolongation from the tendon of the biceps muscle, and by the median basilic vein horizontally crossing the line of the artery. *Behind*, from above downwards, it has the following relations. As the vessel lies inside the humerus, it rests on the long head of the triceps muscle and then on its inner head; inclining to the front, it rests on the insertion of the coraco-brachialis and then on the brachialis anticus muscle, to the bend of the elbow. Thus the artery is supported by muscles throughout its course. At the *outer* side, the brachial corresponds; above, to the coraco-brachialis, overlaid by the biceps, to about the middle of the arm, or opposite the insertion of the deltoid externally; and in the remainder of its extent, to the biceps only, as the vessel lies on the brachialis anticus. In the bend of the elbow, the tendon of the biceps passes down, on the outer side of the vessel. In immediate relation, are two *venæ comites*, one on either side of the artery, and which encircle it with communicating branches; these veins taking the place of the single large axillary vein above, on the inner side of the axillary artery. A superficial vein—the basilic—overlies the brachial, separated by the deep aponeurotic fascia, to about the insertion of the coraco-brachialis, or the middle of the arm; there penetrating the fascia, this vein becomes continuous with the axillary.

Certain nerves grouped around the axillary artery, in its course beyond the small pectoral muscle, still remain in immediate relation with the brachial, and are thus disposed of. The median nerve, lying to the outer side as low as the insertion of the coraco-brachialis muscle, then descends over, or under, the artery, to gain its inner side about two inches above the elbow; and in the bend of the joint, it is placed on the inner side, about half an inch apart, as the vessel inclines outwards to the neck of the radius. This nerve is, otherwise, in contact with the artery throughout its course. The ulnar nerve continues close to the inner side of the brachial artery as low as the insertion of the coraco-brachialis; but there inclining inwards, it passes through the inner intermuscular septum, and imbedded in the triceps muscle, reaches the interval between the olecranon and inner condyle, thus losing all relation to the artery. The internal cutaneous, also to the inner side at first, it then lies over and on the artery as far as about the middle of the arm; there, perforating the deep fascia, it loses this intimate relation; its anterior branch, with the basilic vein, still, however, overlaying the artery. The musculo-spiral nerve remains posterior for about two inches only; then passing backwards and outwards between the inner and outer heads of the triceps, it winds round the humerus and ceases to have any relation to the artery.

Three named *branches* are given off from the inner side of the brachial; the superior profunda, arising near the lower border of the teres major tendon, winds backwards and accompanies the musculo-spiral nerve; the inferior profunda passes off opposite the insertion of the coraco-brachialis, with the ulnar nerve to the interval between the olecranon and inner condyle; and the anastomotic, which arises an inch or two above the elbow, and has the same destination.

*Operation.*—The brachial artery may be ligatured in either part of its course.

In the *first* portion, or that which corresponds to the *coraco-brachialis* muscle, the artery is reached as in the third portion of the axillary, and the brachial being less encompassed with nerves, it is more accessible. An incision along the border of the muscle, and dividing the skin, and fascia, leads down to the vessel. The deep or aponeurotic fascia is then divided, and on drawing the median nerve to the outer side, the artery, with its *venæ comites*, is exposed, with the internal cutaneous nerve to the inner side or in front of the vessel. Separating this nerve, the aneurism-needle may be passed round the artery from either side most convenient to the operator, avoiding, perhaps, the *venæ comites*. But I have frequently included one or both such veins in ligaturing a second-sized artery, and without any evil consequence.

The *second* portion of the brachial—that in relation to the *biceps*—is ligatured in a similar manner. An incision, from two to three inches long is made on the inner border of this muscle (Fig. 70), avoiding the basilic vein; having reached the artery, the median nerve, crossing it obliquely

FIG. 70.

or at the inner side, may be drawn to that side, with the vein. The artery, with its *venæ comites*, will thus be exposed, and the needle readily passed.

The *third* portion of the brachial—that in the *bend of the elbow*—requires ligature only for wound of the artery in this situation. The external wound will guide to the aperture in, or the division of, the vessel; itself lying on the inner side of the *biceps* tendon with the median nerve more internal, by about half an inch.

Aneurismal varix and varicose aneurism at the bend of the elbow, owing to communication of the brachial artery and median basilic vein, are conditions both analogous as to the operation for ligature *in situ*; but they present certain difficulties not met with when the artery alone is wounded. These complications have already been noticed—ANEURISMAL VARIX.

**LIGATURE OF THE RADIAL ARTERY.**—*Surgical Anatomy.*—The radial artery extends from the *bifurcation* of the brachial, opposite the *neck* of the *radius*, to the *end* of this bone; and thence posteriorly through the first interosseous space to the *palm* of the hand. It is thus found in the forearm, the back of the wrist, and palm. In *direction*, the continuation of the brachial, a line drawn from the centre of the bend of the elbow to the styloid process of the radius, will indicate the course of the radial in the forearm. More deeply placed above, between muscles; it becomes quite superficial below as it approaches the wrist.

At first on the inner side of the radius, it soon lies over that bone,

*resting* on the following muscles, in order, from above downwards; supinator brevis, tendon of pronator radii teres, radial origin of flexor sublimis, flexor longus pollicis, pronator quadratus; and on the end of the radius, above the wrist. In the *upper half* of this course, the artery runs *between* the fleshy bellies of the supinator longus externally, and the pronator teres internally, being slightly overlaid by the former muscle; in the *lower half*, it is *between* the tendons of the supinator longus and flexor carpi radialis. The *radial nerve*—a terminal branch of the musculo-spiral in front of the external condyle of the humerus—passes down under cover of the supinator to the outer side of, but not in contact with, the artery as far as the insertion of the pronator teres; then lying by the side of the vessel, the nerve passes backwards under the tendon of the supinator and becomes cutaneous, thus losing any immediate relation to the vessel. Throughout its course in the forearm, the artery is *covered* only by the skin, superficial fascia, and the deep or aponeurotic fascia.

The named *branches* are three. The radial recurrent, a branch of some size, is given off transversely under cover of the supinator longus muscle; it supplies the muscles on the outer side of the forearm, and sends an offset upwards to anastomose with the superior profunda branch of the brachial artery. The superficial volar, and the anterior carpal branches, arise just above the wrist.

Neither of these branches is important in the operation of applying a ligature to the radial trunk, except the first.

*Operation*.—In the *upper* or deeper part—an incision (see Fig. 70) along the inner or ulnar margin of the supinator longus, and through the deep fascia, will lead down to the artery, which is somewhat overlaid by that muscle; its fibres being distinguished by their vertical direction from those of the pronator teres, obliquely crossing the line of incision. Drawing the supinator and with it the radial nerve, outwards; the artery is seen with its *venæ comites*, one of which commonly lies in front. In passing the needle, it is unimportant whether it be included and ligatured.

*Lower down* and superficial towards the wrist; an incision on the outer or radial side of the flexor carpi radialis tendon (see Fig. 70) leads to the vessel, under the deep fascia; lying about midway between this tendon and that of the supinator longus. The radial nerve is here quite out of the way, and the *venæ comites* are unimportant.

On the *back* of the *wrist*, and in the *palm*, the radial is tied only for wound, and at the wounded point. In the former situation, as the artery passes from the end of the radius to the apex of the first interosseous space, it is crossed by the tendons of the three extensors of the thumb, successively; the extensor ossis metacarpi pollicis, and the extensors, primi and secundi internodii pollicis. Either of these tendons may guide to the wounded artery.

LIGATURE OF THE ULNAR ARTERY.—*Surgical Anatomy*.—The ulnar artery extends from the *bifurcation* of the brachial, opposite the *neck* of the *radius*, to the *end* of the *ulna*; thence into the *palm*, to join with the radial in forming the palmar arches, superficial and deep. In direction, it arches from its commencement, inwards towards the ulna, and then downwards; thus not appearing to be the continuation of the brachial, although the ulnar is of larger size than the radial branch. More deeply placed above between muscles, it becomes quite superficial below as it approaches the wrist. At first, it *rests* on the insertion of the brachialis anticus into the coronoid process of the ulna; curving inwards and down-

wards, it lies on the flexor profundus. In the *upper half* of this course, the artery passes *between* the flexor profundus and four, of the five, muscles arising from the inner condyle of the humerus, which overlay and cross the vessel in their direction from within outwards; namely, the pronator radii teres, flexor carpi radialis, palmaris longus, and beneath these three, the flexor digitorum sublimis. Then passing *between* the flexor carpi ulnaris and digitorum sublimis, and overlaid by the former muscle; in its *lower half*, the artery is *between* the tendons of the flexor ulnaris and sublimis, the former tendon somewhat overlaying it. The *ulnar nerve*, entering the forearm between the attachments of the flexor ulnaris to the inner condyle and olecranon, approaches the artery under cover of that muscle, and from about the middle of the forearm, continues down on the inner side of the vessel to the wrist; the nerve being even more concealed by the flexor ulnaris tendon. A small branch of this nerve descends in front of the lower part of the artery, to the skin of the palm; both artery and nerve passing over the annular ligament to the hand.

The *median nerve*, to the inner side of the vessel at its commencement, crosses over to the outer side, and loses all relation to the artery. Throughout its course, the ulnar artery is *covered* by the skin, superficial and deep fascia, as well as by the superficial layer of muscles, above; below, only by the integuments.

The named *branches* of this artery are five; anterior ulnar recurrent, and posterior ulnar recurrent, both arising close to the elbow-joint and passing upwards to complete the anastomosis around the joint; the interosseous trunk, the largest branch given off, passes backwards to the interosseous membrane, there dividing into anterior and posterior branches, metacarpal branch, arising near the wrist; and carpal branches, anterior and posterior, anastomosing with corresponding offsets of the radial, across the front and back of the wrist. Neither of these branches is important in the operation of applying a ligature to the ulnar trunk, except the third or interosseous.

*Operation.*—In the *upper* or deeper part, an incision along the radial border of the flexor carpi ulnaris will lead down to the vessel as it lies between this muscle and the flexor digitorum sublimis; the fibres of the former muscle being distinguished by their more vertical direction from those of the sublimis, obliquely crossing the line of incision. Separating these muscles, the ulnar nerve will probably be out of the way, internally; the artery is seen and the ligature passed. More difficulty, however, may be experienced in a muscular arm, than with the corresponding portion of the radial artery.

*Lower down* and superficial towards the wrist, an incision (see Fig. 70) along the radial side of the flexor carpi ulnaris tendon leads to the vessel, under the deep fascia, and perhaps somewhat overlaid by the tendon. The ulnar nerve, more under cover, is drawn inwards, and the ligature passed between it and the artery.

On the *annular ligament* of the wrist, and in the *palm*, the operation is performed only for Wound, and at the wounded point.

LIGATURE OF THE ABDOMINAL AORTA; AND OF THE ILIAC ARTERIES, COMMON, EXTERNAL AND INTERNAL.—*Surgical Anatomy.*—The abdominal aorta, lying on the bodies of the lumbar vertebræ, inclines downwards to the left, and divides opposite the left side of the *fourth* lumbar vertebra, into two *common iliac* arteries, a right and a left. Either common iliac extends from the *bifurcation* of the aorta at this point, to opposite the

intervertebral cartilage between the fifth or last lumbar vertebra and *base* of the *sacrum*—about two inches in length. It there divides into two trunks or branches, *external* and *internal* iliacs: the external extending from this point, along the *psaos* muscle internally, to the lower border of *Poupart's ligament*; the internal extending from the same point, downwards and outwards on the *pyriform* muscle, to the *sacro-sciatic foramen*, about one inch and a half only in length, and smaller in size than the external iliac.

The relation of the companion veins of these arteries is primarily important in their Surgical Anatomy. For the convenience of description the companion veins may be taken from above downwards.

The *vena cava inferior* lying on the vertebral column to the right of the abdominal aorta, is situated also to the outer side of the right common iliac artery at its commencement; dividing into two *common iliac* veins, the *right* continues on the outer side of the corresponding common iliac artery, and then passes beneath it, the left common iliac vein also passing beneath that artery above. Thus, the right common iliac artery lies on both these veins. The *left* common iliac vein, emerging from beneath the right artery, near the bifurcation of the aorta into both common iliacs, proceeds to the right or inner side of the left common iliac artery. The common iliac veins dividing at, or near, the bifurcation of the common iliac arteries; the *right external iliac* vein passes beneath the right external iliac artery to its left or inner side, where it is found at *Poupart's ligament*; the *left external iliac* vein lies entirely on the right or inner side of the left external iliac artery; and *both* the *internal iliac* veins are posterior to the corresponding internal iliac arteries, the right being somewhat external to its artery. The *muscles* in relation to these arteries are:—the *psaos*, on the outer side of the common iliac, at its termination; and then along the outer side of the external iliac to its termination, where the artery lies on the muscle at *Poupart's ligament*; this muscle is also near the internal iliac at its commencement, the external iliac intervening, while the *pyriform* muscle is behind this artery, on which it rests and on the lumbo-sacral nerve. In *front*, the *peritoneum* overspreads these three arteries, the internal iliac being contained in the fold that forms the posterior ligament of the bladder. Branches of the *sympathetic nerve*, proceeding from the aortic plexus in front of the lower part of the aorta, descend over the common iliacs to the hypogastric plexus in the upper part of the concavity of the sacrum. The *inferior mesenteric* artery crosses the left common iliac. The *ureter* crosses, sometimes the common iliac of its side, but generally the external and internal iliacs, the former at its commencement, the latter lower down. The *external iliac*, near *Poupart's ligament*, is overlaid by the *spermatic vessels* and genital branch of the *genito-crural nerve*, proceeding obliquely inwards to the internal abdominal ring; it is crossed outwards by the *circumflex iliac vein*, and inwards, just above the ligament, by the *vas deferens* turning down on the inner side of the artery. The *abdominal parietes* are interposed between the aorta and iliac arteries and any operation on these vessels. They consist of the skin and superficial fascia; the tendon of the external oblique muscle, the internal oblique and transversalis muscles; the transversalis fascia, and peritoneum, which are loosely connected about the situation of the internal abdominal ring, where the spermatic cord passes through the abdominal walls.

*Operation*.—The iliac arteries, external, internal, and common, and even the aorta, may be reached by the same line of incision; commencing

a little above the middle of Poupart's ligament—where the cord passes through, and carried outwards and upwards, nearly parallel with the

FIG. 71.\*

ligament, to about the anterior superior spine of the ilium, or as far higher as may be necessary (Fig. 71).

(1) To reach the *external iliac*, this incision may terminate near the anterior superior spine. The skin and superficial fascia only are first divided. The bluish-white tendon of the external oblique is next carefully divided to the same extent; exposing the spermatic cord as it passes under the lower margin of the internal oblique and transversalis muscles, in the lower angle of the incision. These muscles should now be divided with great caution, and the dull white transversalis fascia recognised beneath. Raising this fascia with the forceps, at its thinnest and loosest part, near where the cord passes, an aperture is

made, using the knife laterally; the finger should then be gently introduced between the fascia and peritoneum, and the former divided to the full extent of the external wound.

FIG. 72.

The peritoneum, thus exposed, can then be detached with the fingers from its loose cellular connexion in the iliac fossa, and drawn to the middle line, without damaging this membrane. Spatulæ are of use in retaining it there, or the fingers of an assistant may be preferable (Fig. 72). The fawn-coloured artery is seen on the inner border of the psoas muscle, crossed generally by the white tape-like ureter above; unless the peritoneum be raised to a higher point, when the ureter adhering to that membrane, will be raised with it. Lower down the artery is crossed obliquely inwards by the spermatic vessels, and genital branch of the genito-crural nerve. Between these two points,

the aneurism-needle can be passed most readily, with the usual precaution of introducing it between the artery and vein, here below.

\* Letter *a* marks the line of incision for the lower part of the external iliac; *b* shows that for the upper part of this vessel, for the internal, or for the common, iliac arteries.

(2) The *internal iliac* is reached by the same incision, carried a little further upwards and inwards. This artery also is crossed by the ureter, which may be raised with the peritoneum; the companion vein is somewhat posterior, and the external iliac vein outside, at the commencement of the vessel.

(3) The *common iliac* can be reached by prolonging the incision upwards, and curving it inwards, to the extent of six inches; and there is always an advantage in having the incision below near the middle of Poupart's ligament—the loose connexion of the transversalis fascia with the peritoneum, in that situation, facilitating the detachment of the latter membrane and raising it from the artery, which is the most critical part of the operation. The common iliac artery will be found by tracing up the external iliac along the border of the *psoas* muscle. But high up the trunk ceases to have this immediate relation to the muscle, and is most intimately related to venous trunks; on the right side, the companion common iliac vein lying externally, and both it and the left common vein passing behind the artery; while on the left side, the vein lies immediately internal to the artery. Their dark blue colour and large size, contrast with the smaller, fawn-coloured artery. The ureter, like a white band, may perhaps cross the artery on either side; and the inferior mesenteric artery is always in front, on the left side; but generally both it and the ureter are out of the way.

(4) The *abdominal aorta* may be reached in the middle line, as by the operation devised and performed by Sir A. Cooper. Taking the precaution of having the bowels well emptied, an incision was made through the *linea alba*, three inches in length, its centre corresponding to the umbilicus (see Fig. 71, c); the peritoneum was then opened to about the same extent, the intestines, having been emptied, did not protrude. Passing the finger down between their convolutions on to the spine, the aorta was felt beating strongly. The peritoneum was scratched through with the finger-nail, and the finger being insinuated under the aorta, an aneurism-needle was conveyed round it, and the ligature tied.

**LIGATURE OF THE FEMORAL ARTERY, COMMON AND SUPERFICIAL.—**  
*Surgical Anatomy.*—The femoral artery, a continuation of the external iliac, extends from the lower border of *Poupart's ligament* to the aperture in the *adductor magnus* muscle, at the junction of the middle and lower third of the femur, internally. In the upper third of the thigh, the artery lies somewhat internal to the head of the femur; in the middle third, the remaining portion of the vessel inclines to the inner side of the shaft of the femur. In point of *depth* also, the first part is superficial and uncovered by muscle; the second part is deep and covered by muscle—the *sartorius*.

In the *upper third* of the thigh, the femoral artery is contained in Scarpa's triangular space. This space is bounded above by Poupart's ligament, forming the base; and laterally by the *sartorius* muscle on the outer side, and the *adductor longus* on the inner, meeting below in the apex. The artery passes down through the middle of this space, from mid-base to apex. But the length of the space, and consequently of this portion of the femoral, varies with the height at which the *sartorius* muscle inclines inwards and the breadth of that muscle. The artery *lies* on the *psoas* muscle, slightly tilted to its inner side under Poupart's ligament, then over the *pectineus* muscle separated by the profunda artery and vein in cellular tissue, and then on the femoral or companion vein, which

intervenes between the femoral artery and adductor longus muscle at the apex of the space.

Entering Hunter's canal, the artery—in this the *middle third* of the thigh—*lies* on the adductor longus, and lastly, on the adductor magnus, to the aperture of exit in that muscle. The artery is thus slung as it were, close to the femur, on the insertions of these two muscles into the *linea aspera*; and it is bounded externally by the vastus internus muscle, wrapping round the inner surface of the femur to the *linea aspera*.

*Covered* in the *upper third* of the thigh.—Scarpa's triangle, only by the skin and superficial fascia, the deep fascia or fascia lata, and by the inguinal glands; in the *middle third*, corresponding to Hunter's canal, the artery is also covered by the sartorius muscle, lying vertically over its course, and by an aponeurotic covering under this muscle, stretching across between the vastus internus and the tendons of the two aforesaid adductor muscles—thus completing the *canal* through which the artery passes.

The femoral artery and vein, the latter lying to the inner side under Poupart's ligament, are enclosed in a loose tubular sheath, formed by a prolongation in front from the transversalis fascia of the abdominal wall, and behind, from the fascia iliaca; narrowing downwards around the femoral vessels, to about two inches in extent below the ligament, this sheath becomes continuous with the common *cellular sheath* which also invests the vessels *within* the special or *crural sheath*. The outer border of this sheath is straight, the inner oblique; and, from about half an inch below Poupart's ligament, the inner border corresponds to the *saphenous opening* in the fascia lata, itself about one inch and a half in length. The curved *falciform process* of Burns—bounding the outer margin of this opening—is that portion of the iliac part of the fascia lata which overlays the sheath of the femoral vessels; and the *upper corner* of this process stretches inwards to join the base of *Gimbernat's ligament*—thus giving the outer margin of the saphenous opening a direction downwards and inwards. Behind the sheath of the femoral vessels, the pubic or inner portion of the fascia lata passes outwards over the pectineus muscle.

Enclosed within the sheath, the *femoral vessels* are separated by a cellular septum; and another septum to the inner side of the vein, forms a third or inner compartment—the *crural canal*, which is unoccupied otherwise than by a lymphatic gland, excepting when a femoral hernia descends through it to the saphenous opening. The *crural branch* of the genito-crural nerve perforates the outer side of the sheath in *front* of the artery, and then pierces the fascia lata near Poupart's ligament to become subcutaneous. A small *branch* from the anterior crural nerve, above Poupart's ligament, descends *on* the artery. The long, internal, *saphena vein* on the inner aspect of the thigh, enters the saphenous opening to join the femoral vein; and some superficial *lymphatic vessels* also enter this opening to pass through the crural canal to the abdomen.

Continuing the course of the femoral vessels downwards in the thigh, *below* the sheath; the vein still lies to the inner side of the artery, but winding behind it is then found on the outer side, at the upper border of the adductor longus; passing out of Scarpa's triangle, and with the artery entering Hunter's canal, the vein is still to the outer side, and it so passes through the opening in the adductor magnus.

The *anterior crural nerve*, under Poupart's ligament, lies on the outer side of the femoral vessels, but not enclosed in their sheath; being about

half an inch distant, and separated by the tendon of the psoas muscle, on the inner side of which is the artery. The nerve lying in the groove between that muscle and the iliacus externally, it appears as a large, white, flat band, which soon divides into a superficial or cutaneous and a deep or muscular part.

The *superficial* part gives off the middle, and internal, cutaneous nerves of the thigh, and the internal saphenous nerve. The middle cutaneous pierces the fascia about three inches below Poupart's ligament, and dividing into two cutaneous branches which descend on the front of the thigh, it thus loses all relation to the artery. The internal cutaneous inclines obliquely inwards over the femoral artery, and divides into two branches; the anterior, descending on the sartorius muscle to the middle of the thigh, and there piercing the fascia lata; the internal, descending along the inner border of that muscle to pierce the fascia on the inner side of the knee. The internal or *long saphenous* nerve—the largest of the three superficial branches—descends on the outer side of the femoral artery; entering Hunter's canal under the vertical portion of the sartorius, it lies with the femoral vein still to the outer side of the artery, but somewhat posterior to the vein, and external to the cellular sheath containing it and the artery. At the opening in the adductor magnus, the saphenous nerve leaves the femoral vessels on their becoming popliteal; it is continued beneath the sartorius muscle to the inner side of the knee, there to pierce the fascia between the tendons of the sartorius and gracilis muscles. About the middle of the thigh, a communicating branch crosses inwards beneath the sartorius to join an offset of the internal branch of the internal cutaneous, and another from the anterior division of the obturator comes down in front of the adductor brevis to the lower border of the adductor longus. These three offsets here form a sort of *plexus*, beneath the fascia lata.

The *deep* or *muscular* part of the anterior crural nerve divides into a brush of branches, which have more or less relation to the artery externally, towards the apex of Scarpa's triangle. Disappearing under the sartorius to enter the muscles; they supply that muscle, the rectus femoris, the vastus externus, and vastus internus—the branch to this muscle descending near the internal saphenous nerve, which it nearly equals in size; a small branch or two also crosses inwards behind the femoral vessels to the pectineus muscle.

*Branches of the Femoral Artery.*—The superficial pudic—two branches, an upper and a lower—pass inwards over the pectineus muscle, but under the fascia lata, to the skin of the penis, and the scrotum or the labium pudendi; the superficial epigastric, and superficial circumflex iliac pass; the one forwards through the saphenous opening in the fascia lata, and then upwards in the superficial fascia on the lower part of the abdomen; the other branch, outwards across the psoas and iliacus muscles, under the fascia lata, towards the anterior superior spine of the ilium. The *deep femoral branch* or the *profunda* is nearly equal in size to the continuation of the femoral artery after giving off this, the largest branch. Hence the femoral trunk is spoken of as the common femoral artery, this large deep branch as the deep femoral, and the continuation of the common trunk as the superficial femoral artery. The deep femoral arises from the outer and posterior part of the common femoral artery, from an inch to two inches below Poupart's ligament. Inclining outwards over the iliacus muscle—and there giving from its outer side the external

circumflex branch, and near it, the internal circumflex branch from the inner and back part of the vessel—the artery curves inwards and downwards over the pectineus, behind the femoral vessels, to gain their inner side; and passing behind the adductor longus, this deep artery continues down between that muscle and the short and great adductors; there dividing into three perforating branches, which penetrate these muscles close to the linea aspera, to reach the muscles at the back of the thigh.

The profunda *lies*, successively, in front of the iliacus and pectineus, the adductor brevis and adductor magnus, muscles. Placed at first to the outside, and crossing inwards behind the superficial femoral; it then runs parallel to it, but deeper by the thickness of the adductor longus muscle beneath which it passes. The deep femoral *vein* accompanies the course of the artery, but superficial to it; thus being interposed between the deep and superficial femoral arteries. And where the deep artery crosses inwards behind the superficial artery, the superficial femoral vein passes outwards between these vessels; thus making *both* femoral veins *between* the two arteries at that point—about the apex of Scarpa's triangle; just below which, the long adductor muscle separates the arteries and their accompanying veins.

The anastomotic branch, the last-named branch of the (superficial) Femoral, passes off near the opening in the adductor magnus; it gives a superficial offset with the saphenous nerve, and a deep articular one in front of the tendon of the adductor, which arches outwards across the front of the lower end of the femur.

*Operation.*—(1) The *common femoral* artery may be ligatured, by an

FIG. 73.

incision over its course, between the inferior margin of Poupart's ligament and the origin of the deep femoral—about one to two inches below. But the results of this operation have been most unsuccessful, owing to the shortness of the trunk in this situation, and consequent freedom of the collateral circulation.

(2) The *superficial femoral* is easily reached as it passes out of Scarpa's triangle, under the inner border of the sartorius muscle. If the limb be rotated outwards, a line drawn from midway between the symphysis pubis and the anterior superior spine of the ilium, downwards to the inner side of the patella, will about indicate the direction of the vessel. An incision, in this line, three or four inches long and passing over the sartorius, leads to the artery in some part of the incision where that muscle crosses the artery. (Fig. 73.) If the outline of the sartorius be perceptible, as in a thin person, the inner border of the muscle will be the best guide; along

which the incision may be made. Dividing the skin and superficial fascia, and avoiding any large branch of the saphena vein, the thin, bluish-white, fascia lata should then be cautiously divided or slit up on a director to the same extent. A branch of the internal cutaneous nerve may now be seen, and avoided, lying on the sheath of the vessels. The artery, with the vein inclining from the inner side behind it—to gain the outer side—are to be gently separated; and the needle introduced between them. Proper care must be taken to avoid wounding the vein or including it in the ligature; and the usual precaution observed of testing the aneurismal pulsation, by compression with the finger on the presumed artery, before tightening the ligature.

In *Hunter's Canal*, the superficial femoral was originally ligatured by John Hunter for popliteal aneurism, in the operation which he introduced; but it is not practised now-a-days, on account of the difficulty of reaching the artery in this the deep part of its course, compared with the facility of applying a ligature in Scarpa's triangle.

LIGATURE OF THE POPLITEAL ARTERY.—*Surgical Anatomy*.—In continuation of the superficial femoral, the popliteal artery extends from the opening in the *adductor magnus*, over the back of the lower third of the femur and knee-joint, to the lower border of the *popliteus muscle*; where it bifurcates into the anterior and posterior tibial arteries. It thus passes through the popliteal space or ham. In *direction*, this artery inclines from the inner side of the thigh—its lower third—to the middle of the knee-joint, posteriorly, and thence descends vertically to its termination. The *depth* of the vessel is greatest above the joint, and comparatively superficial over it, but deeper beneath the heads of the gastrocnemius muscle, to the lower border of the *popliteus*.

The popliteal artery *lies*, at first opposite to, but not in contact with, the lower third of the posterior surface of the femur, which curving forwards occasions the interval; then, the posterior ligament of the knee-joint; and lastly, beneath the gastrocnemius, on the *popliteus muscle*. The *lateral relations* of the artery are the muscles bounding the popliteal space.

This space is formed by an interval between the attachments of the muscles, behind the knee, to the condyles of the femur. The popliteal space is lozenge-shaped when the muscular boundaries are allowed to fall aside, by removal of the ensheathing fascia lata. The flexor or hamstring muscles of the thigh diverge over the lower third of the back of the femur to their insertion; namely, the biceps, externally to the head of the fibula; the semi-tendinosus and semi-membranosus muscles, internally, to the tibia, the sartorius and gracilis muscles also intervening between them and the femur; below, the fleshy heads of the gastrocnemius converge from their origin above the outer and inner condyles of the femur, and unite just below the joint,—but above the lower border of the *popliteus muscle*. The plantaris muscle also, arising from the line above the outer condyle under cover of the gastrocnemius, forms an additional lateral boundary to the popliteal space, externally.

The popliteal artery extends through the popliteal space, and a little way lower down than its inferior boundary, the united heads of the gastrocnemius, for the artery terminates at the lower border of the *popliteus muscle*.

A small branch of the obturator nerve, from the plexus in the middle of the thigh, descends upon the femoral artery, and into the popliteal space, on the popliteal artery.

The *popliteal vein*, and *internal popliteal nerve*—one of the divisions of the great sciatic—accompany the artery through this space, and beyond it; having the same extent as that vessel, or to the lower border of the popliteus. The vein is superficial to, and in contact with, the artery. Above the joint, it lies somewhat to the outer side of the artery; over the joint, it overlays and conceals the artery between the heads of the gastrocnemius; and under that muscle, it inclines across the artery lying to its inner side at the lower border of the popliteus. The nerve, superficial to the vein, has the same relations to it, and thence to the artery beneath the vein. Thus above, the nerve lies to the outer side of the vein; over the joint, on the vein between the heads of the gastrocnemius; and under that muscle, it crosses the vein—and artery beneath—lying to its inner side at the lower border of the popliteus. The *external popliteal nerve*—the other division of the great sciatic—descends obliquely outwards along the outer side of the space close to the biceps muscle, to just below the head of the fibula; having, therefore, no relation to the artery.

Overlapped above by the muscles, bounding the space, especially by the semi-membranosus, the popliteal artery is thus concealed, as well as partly by the vein and nerve, and also by a quantity of fat in which are imbedded a few small lymphatic glands around the artery; over the joint, the artery—with the vein and nerve—is *covered* only by the skin, superficial fascia, and fascia lata; but below the joint, by the gastrocnemius also, beneath which the small fleshy belly of the plantaris muscle crosses inwards over the popliteal vessels and nerve. The fascia lata ensheathing the limb, holds the muscles together, and conceals the popliteal space; the line of separation between the muscles bounding the space, being indicated only by a slight vertical depression on the fascia lata, in the middle line. The *small sciatic nerve* descending along the back of the thigh, beneath the fascia, nearly corresponds with this depression; and a little below the knee it perforates the fascia to become subcutaneous. The external or *short saphenous nerve*, a branch of the internal popliteal, descends, beneath the fascia, between the heads of the gastrocnemius to the middle of the leg; perforating the fascia, it is joined by a communicating branch from the external popliteal, and accompanies the external saphenous vein. The external or *short saphenous vein* coursing up the back of the leg, in the superficial fascia, passes between the heads of the gastrocnemius, and perforates the fascia there, or lower down, to enter the popliteal vein. It thus lies over the course of the short saphenous nerve, separated by the fascia lata.

The *Branches* of the popliteal artery are not of much importance, surgically. Supplying the muscle, and the joint; the latter branches are the superior articular—inner and outer; the inferior articular—inner and outer; and the azygos which enters the back of the joint through the posterior ligament.

*Operation.*—The popliteal artery is reached by a vertical incision, in the middle line, from about three inches above the centre of the popliteal space and carried down to the extent of four inches. Dividing the skin, superficial fascia, and fascia lata; the tendon of the semi-tendinosus is exposed internally, and the incision continued cautiously along its inner border. The internal popliteal nerve and the popliteal vein are seen, particularly the latter, lying superficial to, and somewhat to the outer side of the artery. Slightly flexing the joint, the semi-tendinosus and semi-membranosus muscles are drawn inwards with a curved spatula; the vein being gently separated from the artery, it is protected in like manner externally, thus bringing the vessel more clearly into view;

and the aneurism-needle should then be passed from without inwards, between the vessels.

**LIGATURE OF THE ANTERIOR TIBIAL ARTERY.**—*Surgical Anatomy.*—The anterior tibial artery extends from the *bifurcation* of the popliteal at the lower border of the popliteus muscle, to the front of the *ankle-joint*; thence to the posterior part of the first interosseous space, it is named the *dorsal artery of the foot*. *Directed*, at first forwards, through the aperture above the interosseous membrane, the anterior tibial passes downwards and forwards to the foot. Situated externally to the shaft of the tibia, in the upper two-thirds of its extent; the artery inclines in front of the tibia, in the lower third.

*Deeply* placed above, between the muscles, in the upper two thirds of its course; it becomes superficial below, between their tendons, and in front of the tibia and ankle-joint.

The anterior tibial artery *rests* on the interosseous membrane, and then on front of the tibia and ankle-joint. It lies *between* the muscles above; first, between the tibialis anticus internally, and the extensor longus digitorum externally, in the upper third of its course; and then between the same muscle internally, and the extensor proprius pollicis externally; but beneath the anterior annular ligament, the tendon of the latter muscle crosses over the vessel to the inner side. The *venæ comites* surround the artery with cross branches, particularly above. The *anterior tibial nerve*—a division of the external popliteal—winds round from below the head of the fibula between it and the peroneus longus muscle, then inwards beneath the extensor longus digitorum, and, between the tibialis anticus and extensor longus, it inclines downwards to the artery about the middle of the leg; crossing the vessel once or twice in its course, the nerve is still external at the ankle-joint.

*Overlapped* laterally, by the fleshy bellies of the three muscles between which it lies; the artery is *covered* only by the skin, superficial fascia, and aponeurotic fascia; but beneath the anterior annular ligament, it is crossed by the tendon of the extensor pollicis from without inwards. The aponeurotic fascia is attached to the crest or spine of the tibia and to the outer margin of the shaft of the fibula; thus binding down the muscles in their relative position. Intermuscular septa, indicated by white vertical lines, pass in between the muscles dividing them into three groups; an anterior extensor group of three, between the shafts of the tibia and fibula; an external or peroneal division of two, on the outer surface of the fibula; and the flexor muscles, on the back of the leg. The extensor muscles are separated by an intermuscular septum between the tibialis anticus and extensor longus digitorum. This septum can be readily recognised through the integuments when the foot is extended, the fleshy bellies of the muscles above rising up, and thus indicating the line of the septum. The anterior annular ligament of the ankle, a thickened portion of the aponeurotic fascia, consists of an upper and lower portion; in the latter there are three sheaths for the tendons of the extensor muscles—an inner one for the tibialis anticus, an outer for the extensor longus digitorum, and a middle, intermediate sheath for the extensor pollicis. The artery behind the latter tendon, is separated from it by the sheath.

The *branches* of the anterior tibial artery are, muscular offsets, and named branches; the recurrent, ascending in the tibialis anticus to the knee-joint; and malleolar, internal and external, which pass horizontally over the ends of the tibia and fibula.

The *dorsal* artery of the foot, continuing the anterior tibial from the front of the ankle-joint to the posterior part of the first interosseous space, sinks into the sole of the foot to communicate with and complete the plantar arch. In its course, the artery *rests* on the astragalus, scaphoid, and internal cuneiform bones; it lies *between* the tendon of the extensor pollicis internally, and the inner tendon of the extensor brevis digitorum externally, as far as about half an inch before the artery sinks into the sole, where this tendon crosses obliquely over to the inner side; the vessel is *covered*, otherwise, only by the skin, superficial, and aponeurotic fascia, here a very thin membrane. Two *venæ comites* accompany the vessel, also the anterior tibial nerve, which still lies external; becoming cutaneous in the first interosseous space, to supply the opposed sides of the great toe and the next.

The *branches* are—a tarsal branch, which arises opposite the scaphoid bone, and passes under the extensor brevis to the outside of the foot; and a metatarsal branch, which forms an arch across the foot, under the extensor, near the bases of the metatarsal bones.

*Operation.*—The intermuscular septum is the best guide to the anterior tibial, between the fleshy bellies of the tibialis anticus and extensor communis, and continued down between the former muscle and the extensor pollicis. Or, a line drawn from the inner side of the head of the fibula to the centre of the ankle, will indicate the vessel, throughout its course.

In the *upper third* of the leg; an incision from two to three inches in length, between the extensor communis and tibialis (Fig. 74), leads down to the artery, deeply placed under cover of the latter muscle. The anterior tibial nerve, distant to the outer side, is here out of the way. On drawing the tibialis muscle in-

FIG. 75.

FIG. 74.

ward, the artery is seen with its *venæ comites*, and the ligature may be passed from either side of the vessel. (Fig. 75.)

In the *lower two-thirds* of the leg; an incision, less in length and depth, will find the artery between the less fleshy portions, or between the tendons, of the extensor pollicis and tibialis anticus (see Fig. 74);

but in the lower third, the artery inclines in front of the tibia, with the tendon of the former muscle approaching to cross over it. The anterior tibial nerve, from about the middle of the leg, may be seen accompanying the artery and its *venæ comites*. Drawing the tendons aside, with the nerve, the vessel is easily ligatured from either side.

The *dorsal artery* of the foot can be readily reached by an incision along the outer side of the tendon of the extensor pollicis (see Fig. 74), dividing only the skin, superficial fascia, and aponeurosis. The artery is seen between this tendon and the inner tendon of the extensor brevis digitorum, externally, or which may pass over it to the great toe.

**LIGATURE OF THE POSTERIOR TIBIAL ARTERY.**—*Surgical Anatomy.*—Continuing the popliteal artery from its *bifurcation* at the lower border of the popliteus muscle, the posterior tibial thence extends to the lower border of the *internal annular ligament*; there terminating in two plantar arteries for the sole of the foot. Its *direction*, at first, is vertical midway between the tibia and fibula, but inclining inwards it descends over the lower end of the tibia, posteriorly, and then in the middle of the hollow between the inner ankle and heel. Very *deeply* placed above, under the muscles of the calf, it becomes more superficial, behind the tibia, and inner malleolus.

The posterior tibial artery *lies*, at first on the tibialis posticus muscle, but passing inwards, on the flexor longus digitorum and lower end of the tibia and ankle-joint. In the upper half of its course, the artery lies *between* the tibialis posticus and the fleshy bellies of the gastrocnemius and soleus muscles, which conceal it; in the lower half, it lies between the tendo-Achillis and inner margin of the tibia. Behind the inner malleolus, the tendon of the flexor longus pollicis is external, and the tendons of the tibialis and flexor longus are between the artery and the malleolus. Two *venæ comites* surround the artery with cross communicating branches. The *posterior tibial nerve*, a continuation of the internal popliteal at the lower border of the popliteus muscle, lies internal to the artery for about one inch and a half; but crossing to its outer side, it continues to have that relative position down the leg to the interval between the malleolus and heel, there lying immediately to the outer side of the vessel, between it and the tendon of the flexor pollicis.

*Covered* by the gastrocnemius and soleus muscles, as far as the middle of the leg; the artery below is covered only by the skin, superficial and aponeurotic fascia. The annular ligament—a thickened band of the aponeurosis—stretches across between the inner malleolus and os calcis. It sends inwards three sheaths for the tendons of the flexor muscles; an inner one for the tibialis posticus, behind which is another for the flexor longus, and externally, near the os calcis, is a third for the flexor pollicis.

*Branches*—The *peroneal*, almost equal in size to the posterior tibial, arises about one inch and a half below the border of the popliteus muscle, where the posterior tibial nerve crosses the artery to the outer side; passing outwards between the muscles to the fibula, it descends somewhat under cover of that bone and in the fibres of the flexor pollicis, to the aperture below the interosseous membrane; there sending a branch forwards, and another between the tibia and fibula to the outer side of the foot. Other branches of the posterior tibial are of smaller size; some are muscular in the course of the artery, and an anastomotic communicating branch passes outwards across the lower end of the tibia.

*Operation.*—*High up*, under cover of the gastrocnemius and soleus muscles, the posterior tibial may be reached by a free incision between

the margin of the tibia and the gastrocnemius. (Fig. 76.\*) This incision must be continued down to the tibial origin of the soleus, which is then to be divided; both these muscles are drawn back, aided by flexure of

FIG. 76.

the leg and extension of the foot to relax the muscles; the artery with its venæ comites will thus be found, and the nerve to the outer side or crossing to that position. (Fig. 77.) The introduction of an aneurism-needle and securing a ligature, may prove very difficult, owing to the depth of the vessel. This operation was condemned by Mr. Guthrie, as "difficult, tedious, bloody, and dangerous;" and he proposed a substitute, which was practised by Mr. Arnott in a case where he

ligatured the posterior tibial artery for a wound of that vessel, high up.

Having applied a tourniquet to the femoral or popliteal, an incision six or seven inches long, is made down the middle of the calf of the leg, over the skin-wound, as nearly as possible, or leading down to the artery

FIG. 77.

at its wounded point. The gastrocnemius and soleus muscles must be divided freely, their opposed surfaces being recognised successively as tendinous expansions; the under surface of the soleus having been reached, the muscles are held aside with curved spatulæ, and a thin bluish-white aponeurotic septum between the muscles of the calf and the tibialis posticus, comes into view. Immediately beneath this septum the posterior tibial vessels and nerve will be found, lying on that muscle. But, as in the arm, the horizontal process of the aponeurotic fascia which thus separates the superficial and deep layer of muscles, is commonly very indistinct and indeed merely cellular in the upper part of the leg.

Scraping away this thin membrane, the artery is ligatured above and below the wounded point, including, probably, the venæ comites and some surrounding muscular tissue.

Low down, behind the inner malleolus, the artery can be readily secured by an incision midway between the malleolus and the tendo

\* The line of incision in this Fig. is more adapted for the lower half of the artery.

Achillis. (See Fig. 76.) Dividing only the skin, superficial fascia, and aponeurosis, the artery is found with the nerve to its outer side. By extending the foot, and turning it slightly inwards, to relax the flexor and tibial muscles, the ligature can be at once passed and tied.

The *peroneal* artery may be reached by an incision along the outer border of the fibula, between it and the gastrocnemius. The flexor longus pollicis must then be either partly divided or drawn outwards, when the artery will be found in the fibres of that muscle and running close under the fibula. The ligature must be passed as best the Surgeon may be able. This operation, like that on the posterior tibial higher up, is more easily described than done.

## CHAPTER XXVI.

### DISEASES OF ARTERIES.

**ARTERITIS.**—*Structural Conditions.*—Inflammation of any portion of the arterial system produces structural alterations in the coats of the vessel, similar to those resulting from inflammation of any other texture. Increased vascularity, and interstitial exudation of fibrinous matter, renders the coats of a bright red colour, thickened and pulpy; the interior of the artery, in particular, has a crimson hue, as though some irritating fluid had been injected into the vessel, and it is lined with a slight lamella of lymph here and there, whereby the coats becoming fused, the vessel loses its elasticity. The blood within the vessel undergoes coagulation and forms a plug which more or less completely blocks up the vessel, thus rendering it impervious as a blood-conveying tube, and below which the calibre of the artery is somewhat contracted. This plug, conical in shape, consists partly of yellowish fibrinous exudation, occupying its base and adhering to the interior of the vessel, and partly of ordinary black coagulum, which forms apparently on this inflammatory portion, and, tailing off to some distance, is not adherent to the vessel. This condition is denominated *Adhesive Arteritis*. Inflammation, with the secretion of pus, instead of fibrine, from the interior of the vessel, may perhaps occur sometimes, and it is probably of a spreading character; but whether the purulent matter be true pus, or disintegrated fibrine, remains, I think, to be determined by further observation. This condition constitutes the *Suppurative* and *Diffuse Arteritis* of some authors.

The *Symptoms* of Arteritis are referable both to the vessel affected, and to the part which it supplies with blood. Induration, and a cord-like feeling of the vessel when passed under the finger, arises from the thickening of its coats, and coagulation within the tube. Pain of a remarkably twofold character is experienced—a superficial sensitiveness of the skin over the artery, and a deep burning or lancinating pain in the course of the vessel, and striking through the limb. But any redness or heat in the inflamed part will scarcely be perceptible. The pulsation is peculiarly thrilling or jerking, but diminishing, it at length ceases. Below the part supplied by the vessel, the temperature declines, accompanied with a sensation of weight and fulness, and a loss of voluntary power. Gangrene is imminent. The *general* symptoms are those of inflammatory fever, speedily subsiding into prostration.

*Causes.*—Arising usually from some form of injury—a blow, a strain, a wound, or the application of a ligature, arteritis may also proceed from some constitutional condition of obscure nature. Some blood-condition, probably, representing what is termed a broken constitution, seems to be the cause of the diffuse form of arteritis. The traumatic and constitutional modes of origin may co-operate.

*Course and Terminations.*—(1) Absorption of the coagulum may take place, the artery regain its natural calibre, and the circulation be fully restored. (2) Or the coagulum remaining and extending, gangrene, in the dry form of mortification, supervenes, the artery undergoing contraction and obliteration as a fibro-cellular cord. Gangrene may be prognosticated, in proportion to the degree of occlusion, its suddenness, and the size of the arterial trunk. Absorption, or rather, transmission of the fibrinous exudation in a state of disintegration, or of pus if secreted, would seem to occur in some cases, and give rise to the symptoms of *Pyæmia*. This event is, perhaps, more especially incident to diffuse arteritis.

*Treatment.*—Local blood-letting, by means of leeches applied in the course of the vessel and warm fomentations, will be appropriate, followed by calomel and opium, to prevent fibrinous exudation, and alkaline salines to promote disintegrative solution of the coagulum. But certain measures, remedial in relation to inflammation or its consequences in other textures, are here inappropriate; the arterial system, in part at least of its extent, being itself the seat of inflammation. Thus, stimulants, in their beneficial influence on the general circulation, might increase the exudation of fibrinous matter within the vessel inflamed, and induce gangrene. Stimulating applications also, as mercurial inunction, to promote absorption of the exudation would be similarly hazardous.

The treatment of gangrene, medicinally, and with reference to amputation, and also of any pyæmic symptoms, presents nothing peculiar.

*OSSIFICATION OF ARTERIES.—Structural Condition.*—Ossification or calcareous degeneration of the coats of arteries—as relating to the principal arteries of the leg—was noticed by Thomson and Hodgson, in connexion with the dry form of mortification of the toes and feet; and which being incident to old age, or premature old age, is known as Senile Gangrene. Sir B. Brodie more particularly investigated the pathology of this disease, and according to his observations, the structural changes are summarily these:—In the leg, calcareous degeneration of the larger arteries, and fibrous thickening of the smaller ones, are accompanied with more or less contraction of the vessels, and perhaps the coagulation of fibrine within them; conditions which, together, produce a partial or complete obliteration of the channels through which arterial blood should be supplied.

*Symptoms.*—In either or both legs; numbness, coldness, and weakness arising from a defective supply of arterial blood; these symptoms come and go; they are present, whenever circumstances demand a more active circulation, which the unyielding arteries cannot allow; absent when a sluggish circulation is sufficient. Thus, rest, posture, and warmth may maintain this sufficiency; while active exercise, and any posture or pressure that further impedes the circulation is soon attended with a sense of weakness in the limb, numbness, and coldness. Flying pains in the limb, or fixed pain in a spot, are sometimes experienced. Under

these functional symptoms, as affecting one or both legs, gangrene is always more or less imminent.

*Senile Gangrene.*—Commencing, generally, on the pulpy portion of one or more of the toes, a port-wine red colour or a black discoloration appears, preceded by inflammation, or by a stinging sensation, or by numbness and coldness, as *premonitory* symptoms; but frequently without any such precursory local symptom. Soon a vesicle arises over this discoloured spot, or more than one vesicle. The vesicle or vesicles burst, disclosing the true skin in the blackened state of sphacelus. It is encircled with a dusky red hue. This death-warrant advances, perhaps, slowly, extends over the toes and back of the foot, uniformly and symmetrically, followed up by the black shade of sphacelus. Spreading up to the instep, senile gangrene presents the appearance as if the foot were thrust into a black slipper trodden down towards the heel. The dead part is black, shrunken, and mummified—the very type of *dry* gangrene. If both feet be affected, a pair of black hoofs is presented. (See Fig. 30.) It spreads to a variable extent; gaining the ankle, life usually succumbs to the consequent constitutional depression; occasionally, it may extend as high as the knee, or even to the thigh. But the possible extent is unknown, and cannot be determined during life, the causative condition of the arteries being undeterminable. Nature alone decides the “line of demarcation” betwixt the living and dying parts. The accompanying constitutional disturbance or fever, is of the typhoid type.

*Causes.*—The inelastic, and contracted or obliterated state of the arteries, is the structural cause in operation; but this is, frequently, a *predisposing* condition, although maintaining the gangrene when established. Some slight injury to the foot—an abrasion, scratch, or wound—is commonly the *immediate* cause, the gangrene being so far *traumatic*. Sir B. Brodie offers a reasonable explanation. During inflammation, an increased supply of arterial blood is required, and the arterial trunks leading to the inflamed part become dilated so as to permit this extra quantity; but, when these vessels are ossified, they lose their dilatability and power of accommodation, the greater supply of blood demanded by inflammation is withheld, and the part perishes. *Age* is certainly a *predisposing* cause, in virtue of the degenerative changes which the arteries, in common with other textures and organs, undergo as life advances. Hence, ossific degeneration of the arteries is liable to occur in persons past the middle period of life, say fifty years of age; those who are old in years, or in those who are prematurely old for their years. Either sex is liable to this degenerative change, though perhaps not equally so.

The *duration* of senile gangrene is uncertain. It may continue for a few weeks or months, even a year, and terminate fatally. Or, if limited to a toe or two, the part may be detached naturally, by the formation of a line of demarcation and ulcerative severation, or, be removed surgically; and in either case, the patient recovers.

*Treatment.*—*Preventive* measures—in those who have had, from time to time, premonitory symptoms—will consist, in the avoidance of the circumstances, which disturbing the circulation, are the immediate causes of senile gangrene. Hence, attention to rest, posture, and uniform warmth of the legs by clothing; gangrene commencing usually, after a walk, long standing, or exposure to cold. Then again, the Surgeon should avoid the slightest operation, even the laying open of a sinus on the foot; if the patient has been subject to premonitory symptoms. Sir B. Brodie relates

a case in his early practice, where such an operation—trifling in itself—gave rise to inflammation, gangrene of the whole foot on the following day; and in two days more, death ensued.

The treatment of (senile) *gangrene*, is both local and constitutional. The *local* indication is, to solicit the formation of a line of demarcation or limitation of the gangrene, and thus also restrict the extent to which it might otherwise have spread. Hence, to maintain the temperature of the foot or feet, in order to diffuse the local circulation and sustain the vitality of the part; a condition necessary for Nature to declare the line of severation between the living and dead portions. Cotton-wool padding, deeply enveloping the limb, is most effectual; and it need not be reapplied for some days, the gangrenous part being previously covered with lint soaked in chlorinated, carbolic, or other antiseptic lotion. *During* the process of separation, reparative closure of the vessels, by adhesive inflammation, should be promoted by poulticing or an epithem of spongio-piline soaked in warm water. When the soft textures are detached; the bones may be sawn through, and the otherwise natural amputation aided by this amount of surgical interference. Any earlier, or more actual amputation, might or would excite inflammation and thus perhaps start the gangrene afresh. The *ulcer* left by the part removed, is a simple or healthy, healing sore. Thence, during granulation and cicatrization, water-dressing may suffice, or a slightly stimulant lotion, as balsam of Peru, pure or diluted, with an equal part of yolk of egg. Subsequently, the internal cause of gangrene, ossification of the arteries, still being persistent; exposure to cold must ever be avoided, and the circulation cherished by the patient wearing thick woollen socks and flannel drawers.

*Constitutional* treatment will depend on the stage of the disease. During the *typhoidal* fever, consequent on gangrene, prior to closure of the vessels; supporting measures are indicated, an easily assimilated diet of principally animal food, with malt liquor, and wine or alcoholic stimulants. Bark, ammonia, and chlorate of potash are accessory only as a medicinal tonic and stimulant. Opium is peculiarly efficacious; the tincture, in small but repeated doses, to the amount of two to four grains in the twenty-four hours, and increased as the system is brought under its influence. Headache, or disturbance of the digestive organs, will contra-indicate its use, or suggest its discontinuance. During the *inflammatory* fever which accompanies occlusion of the vessels, in the separation of the gangrenous part, or when otherwise present; opium should still be administered, to suppress the nervous excitement, while it sustains adhesive inflammation; and the general circulation and strength be supported by moderate diet, with a mild tonic and stimulant plan of treatment. Topical measures to regulate the inflammation, would probably provoke gangrene.

## VEINS.

## CHAPTER XXVII.

INJURIES.—VARICOSE VEINS.—PHLEBITIS.

WOUNDS OF VEINS.—See WOUNDS, Ch. XIV.

ANEURISMAL VARIX, AND VARICOSE ANEURISM.—See ANEURISM, Ch. XXIII.

VARICOSE VEINS, OR VARIX.—*Structural Conditions, and Diagnostic Characters.*—Varix signifies, an enlarged, elongated, knotty, and tortuous condition of the veins of a part; the knotty enlargements corresponding to the sinuses behind the valves in these vessels. Thickening or thinning of the coats of the veins, at different points, and destruction wholly or partially, of the valves; accompany these more perceptible changes of size and outline.

Certain more *minute* changes in the coats and valves of varicose veins, are thus described by Hassie; changes which constitute *different forms* of varix, and represent the order of their occurrence.

“In persons affected with a morbid preponderance of the venous system, we first of all observe an undue prominence of the veins of the skin. These appear in *dense nets* of branches, remarkable for their diffuse distribution, and are generally turgid with blood, or liable to become so from the slightest mechanical or dynamical causes—like what, under ordinary circumstances, would be the effect of violent and prolonged muscular exertion. In this condition of the veins, their *coats* have not undergone any absolute change, being everywhere proportionate to the width of the calibre; the vessels are not more than usually tortuous, and cannot as yet be called morbidly altered.

“After a while, however, they become permanently *dilated*, an occurrence more frequent in elderly than in young persons. This is brought about by a reinforcement of the fibrous texture of their *external coat*, in the shape of an accession of conspicuous transverse fibres. Meanwhile the internal membrane remains unchanged in structure, merely displaying numerous lines or superficial furrows running lengthwise, and the vessel still maintains its natural course, not assuming a more sinuous, but rather a straighter direction. It does not collapse, on section, but remains patent, and is distinguishable from the arteries by its colour, which is of the same pale-red as the fibro-felt texture constituting the normal external membrane of a vein. The *valves* remain unaltered. In this condition the saphena is frequently found in old persons, so also are certain branches of the vesical plexus, while other branches manifest still further changes.

In the greater number of instances, however, the external membrane of the vein is not thickened, but, along with the other membrane, undergoes considerable *attenuation*, in proportion as the vein becomes more and more dilated. Conformably with their irregular disposition, the intermediate fibres give way unequally, allowing the internal membrane to jut

out in *sac-like protrusions*, and to establish so many irregular, constricted, pear-shaped, and often in appearance, pediculated tumours. At the commencement of some of the smaller branches, the membrane thus forms pouch-like dilatations, or forces itself between the longitudinal fibres of the external membrane in lengthly protuberances, which exceed in circumference that of the vein in its natural state; or, it may, perhaps, distend cylindrically and pretty equably for a considerable length the intermediate fibres before alluded to. Meanwhile the *valves* become attenuated, and pulled asunder transversely, so as to be useless; in many instances they become partially or wholly obliterated, and are torn into shreds, or destroyed as far as their free border, which then runs across the diameter of the vessel like a filament or band, attached by the two extremities to the internal membrane. The veins now appear *elongated*, and their course very *tortuous*." The *blood*, at first fluid, is liable to undergo coagulation, occluding the channel of a varicose vein. A sensation of weight, fulness, and even pain, accompanies this double obstruction to the venous circulation—varicosity of, and coagulation within, the veins. But the symptoms referred to are not peculiar to this condition; and they are increased by exercise and the erect posture.

The veins most liable to become varicose, are, the subcutaneous and submucous. The internal saphena, and less so, the external saphena, are peculiarly liable; and form the varicose veins commonly seen. Less commonly affected, are the veins of the arms, abdominal parietes, the chest, external jugular in the neck, and the superficial veins of the head. The lower hæmorrhoidal veins around the anus, and the lower portion of the rectal mucous membrane, are frequently varicose; forming hæmorrhoids or piles, external or internal. The spermatic veins, around the cord in the scrotum, are not unfrequently affected, when the disease is named varicocele. Of deep-seated veins, those most liable to become varicose are, the internal jugular, the *venæ azygos*, and the prostatic veins.

*Causes.*—Any occasion of pressure on a venous trunk; or any cardiac obstruction to the free return of venous blood, or want of propulsive power of the heart, will induce varix. The veins of the lower extremities are so commonly the seat of this condition, owing to their distance from the heart, and the influence of gravitation. Habitually excessive walking exercise, or a standing occupation, operate in like manner. Wearing a tight garter below the knee, and the enlargement of the uterus during pregnancy; well illustrate the production of varicose veins by pressure, on the saphena or iliac veins. Disease of the liver and rectal constipation have a similar relation to hæmorrhoids. Certain *predisposing* causes may be noticed. The want of support by surrounding textures, predisposes superficial veins to become varicose. It is said that some degenerative change in the coats of veins, as in the arteries, may also be a provocative condition. Age has certainly a notable influence; the disease being rare in early life, and increasing as years advance. Sex seems to have some influence; varicose veins occurring more frequently in women; probably, chiefly, in connexion with the uterine conditions of pregnancy or the formation of a tumour.

*Course and Terminations.*—(1) Inflammation of the vein is very apt to supervene, and by increasing the liability to coagulation within the vessel, lead to further consequences; persistent œdema of the sub-cellular tissue, and ulceration, forming the *varicose ulcer*. (2) *Venous hæmorrhage*

may ensue, sometimes of an alarming character, in the event of this ulceration extending into the vein, or some large branch. Similar hæmorrhage may proceed from attenuation and bursting of a varicose vein.

*Treatment.*—The removal of any cause in operation; as any occasion of pressure or obstruction, will, of course, be the primary rule to be observed.

*Palliative* measures consist in rest, elevation of the part, and moderately firm, even, and continued compression of the veins, by means of bandaging with an elastic roller. (Figs. 78, 79.) These figures both show the mode of applying a roller-bandage to the leg. Commencing from the toes, each turn of the roller is made to *overlay* the preceding one, so that no intervals are left between the turns, through which the integument would become swollen; the turns are made with moderate, but *even* firmness, by a slight pull in completing each circle;

FIG. 78.

FIG. 79.

and *cross-turns* are made as the roller is carried up the leg, in order to adapt the bandage evenly to the increasing circumference of the leg—this manipulation being effected over the tibia by just fixing the bandage with the thumb of the left hand, as the cross-turn *downwards* is made, in carrying the roller around the leg. Fig. 79 also shows another mode of applying the bandage around the heel, and the previous cross-straping of a *varicose ulcer*, which often co-exists with varicose veins. Or an elastic stocking may be worn, as another mode of affording support to the enlarged and weakened veins. These appliances relate specially to varicose veins of the lower extremities; but a similar mode of treatment is applicable generally.

Varicocele and Hæmorrhoids are specially noticed in connexion with Diseases of the Scrotum and Rectum, respectively.

*Radical or Curative Treatment*, consists in obliteration of the Vein or Veins, by various operative procedures. They are none of them more than occasionally successful, and some are hazardous rather than curative.

The *twisted suture* may be applied at intervals along the course of the

vessel; with *subcutaneous* section of the portion of vein included between any two such sutures, placed about one inch apart. (Fig. 81.) The subcutaneous section is made with a fine narrow-bladed tenotomy knife—

FIG. 80.

straight or curved, as may be convenient. (Fig. 80.) The point of the knife is entered under the vein, and carried to the opposite side to just beneath the skin; then, by drawing the blade outwards, so that the point traverses a semicircle under the integument—as felt by the forefinger of the other hand, the vein is thus divided—its thickened structure cutting with a leathery resistance. This operation has already been

FIG. 81.

described in the treatment of Varicose Ulcer. It is the most successful, and least objectionable mode of obliterating varicose veins. In no case but one, have I seen any untoward event—sloughing, phlebitis or pyæmia; and in some cases, the cure has been permanent. It is the only mode of obliteration which I have recourse to. The suture part of this proceeding originated, I believe, with Velpeau; the subcutaneous section additionally, is due to Mr. Lee.

*Subcutaneous* section of the vein, without placing a suture-barrier on either side of the divided portion to guard either aperture, is always perilous; owing to the risk of pyæmic infection consequent on any phlebitis, which may thus be excited. *Excision* of a small portion of the vessel, is equally hazardous, as attested by Sir B. Brodie.

*Cauterization*, to excite inflammation of the vein, may be effected by the application of caustic potash or chloride of zinc, so as to produce eschars in the course of the vessel—the phlebitis advancing to adhesion, and stopping short of suppuration, within the vessel. But thence the risk of pyæmic infection. Yet this mode of inducing obliteration has been recommended by Seutin, Bonnet, and other Surgeons; and is particularly advocated by Mr. Skey, within certain limitations. He recommends the application of Vienna paste; potash in the proportion of two parts with three of lime, and spirits of wine being added to form a paste. The eschars should not exceed the size of a split pea, and their number be regulated by the extent of the varicose vein. Thus produced and restricted, they are said to be free from danger.

*Injection* of a few drops of the perchloride of iron, and the influence of *galvanism* transmitted through needles introduced into the vein, are modes of obliteration so questionable as to their efficacy, or their safety, that they need only be mentioned.

*Venous hæmorrhage*, occurring in the course of varicose veins; the bleeding may be arrested, temporarily, by digital compression—slight pressure with the point of the finger being quite sufficient; and per-

manently arrested, by a compress of lint, secured by a bandage, over the aperture in the vein, with elevation of the limb.

**PHLEBITIS.**—*Structural conditions.*—Inflammation of any portion of the venous system, produces structural alterations in the coats of the vessels similar to those resulting from inflammation of an artery. It may be *Adhesive* or *Suppurative*, but more commonly the latter; and both forms of Phlebitis are far more common than Arteritis.

The coats of an inflamed vein have a dark red colour, and have become thickened and pulpy owing to an interstitial fibrinous exudation; the inner coat, in particular, presents this hue—partly due to the imbibition of colouring matter from the blood, and a lamella of lymph is adherent to the surface. The blood within the vessel has undergone coagulation, more or less perfectly, forming a hard or soft blackish coagulum, mingled with the fibrinous exudation. Thus far phlebitis is *adhesive*. But, pus being readily secreted within the vessel; *suppurative* phlebitis may soon be established. If limited within the boundary of the coagulum and fibrinous exudation, above and below—the pus lying between the coats of the vessel and the coagulum, and between interrupted portions of the coagulum; this circumscribed form of suppuration has been named *limited suppurative phlebitis*. And, as the matter, thus occluded or imprisoned cannot be transmitted into the general circulation; this condition is not productive of pyæmic infection. But, if the plastic lymph-barriers within the vessel, above and below these collections of pus, give way; *diffuse* suppurative phlebitis ensues, and pyæmia will be inevitable. *Diffuse* phlebitis signifies a spreading form of the disease, but as this character is probably never unaccompanied by suppuration, the distinction seems unnecessary.

The *Symptoms* of Phlebitis are referable both to the vessel or vessels affected, and to the circulation in the part below. An inflamed vein is hard, cord-like, and knotted, under the finger, painful or tender on pressure; and a purplish redness with some degree of heat, may be perceptible in the course of the vessel. If the vein be varicose—a pre-existing condition not uncommon—these symptoms may be even more marked, and those of varix are superadded. The supervention of *suppuration* is denoted, in the limited or circumscribed form, by the symptoms of abscess in exchange for those of purely adhesive phlebitis. One or more small fluctuating swellings appear in the course of the vein; instead of its previously, uniformly hard, cord-like character, which thus becomes more knotty—hard here, and softened there. In the *diffuse* form of suppuration, the whole tract of the vessel softens down uniformly; fibrine, coagula, and pus commingling.

Obstruction to the venous circulation, arising from the fibrinous exudation and coagulation within the vessel, produces some œdema in the part below, or general swelling of a whole limb, if a large venous trunk be the seat of obstruction. In adhesive phlebitis this swelling will be *most* conspicuous. No blood passes through the femoral vein, for example, in this condition of phlegmasia dolens; an arrest of circulation which soon tells on all the tributary veins throughout the limb. Its cellular texture becoming gorged with serum, the whole limb is swollen, tense, and hard; of a polished, pearly-white colour, or mottled, cold and insensible—a marble limb, and much larger than its fellow. The *general* symptoms are those of inflammatory fever, very shortly subsiding into prostration; and pyæmia—as a consequence of diffuse suppurative phlebitis.

*Causes.*—Some form of injury is, commonly, the immediate cause of phlebitis; a wound, as in operations involving the veins, phlebotomy, or the application of a ligature. Some constitutional or blood-condition, probably, predisposes, or may be the predominant cause, in most cases. This causative condition is apparently akin to that of erysipelas.

*Course and Terminations.*—(1) Absorption seems to prevail in some cases; the coagulum becoming centrally pervious, and a channel thus forming, through which the venous circulation is re-established. (2) Or, obstruction continuing, the vessel becomes impervious, and, shrivelling into a fibrous cord, is obliterated; Gangrene threatens; in proportion to the degree of occlusion, its suddenness, and the size of the venous trunk. Such are the consequences of *Adhesive* phlebitis, more especially. *Suppurative* phlebitis may proceed to further consequences, local and constitutional. (3) Rupture of the vein, with the formation of abscess in the surrounding cellular texture, and sloughing. (4) Pyæmia is announced by rigors, great prostration, rapidity of pulse, with other symptoms of purulent infection; followed frequently by a fatal issue.

*Treatment.*—Local blood-letting, by means of leeches applied along the course of the vessel, and warm fomentations, may prevent adhesive phlebitis; by promoting resolution of the inflammation before fibrinous exudation and coagulation have supervened. Subsequently, alkaline salines may induce disintegration and absorption of materials occluding the vessel. But the administration of calomel and opium is of doubtful efficacy. Fibrinous exudation may, indeed, be thus prevented, in some measure; but the peril of *diffuse* suppuration will be facilitated. *Abscess* arising, it must be opened forthwith; and chronic œdema may be restrained by bandaging, or removed by blisters. Stimulants are more needed, and earlier, than in Arteritis; and they are less objectionable with relation to gangrene, which is rather a tendency only of the disease, than actually resulting from venous obstruction. *Pyæmia* cannot be overcome by any known remedial measures. Besides the treatment by opium, wine, or brandy, and egg mixture, freely administered; Pirrie recommends the tincture of the muriate of iron, in doses of 25 drops every 4 hours.

**PHLEBOLITHS, OR VEIN-STONES.**—Small concretions are not unfrequently formed within various veins, more particularly in the iliac and its branches. These bodies are either free, or attached to the interior of the vessels, cropping in and gathering fibrine around themselves as the stream of blood eddies slowly by. One such body, situated in a principal vein, as either common iliac, might become a cause of serious obstruction to the return of blood from the whole lower extremity.

The *diagnosis* would be difficult or impossible, the occluding concretion being discovered only after death. Fortunately, however, when venous obstruction is gradually established, an adequate compensation is provided by the simultaneous enlargement of other veins, as collateral channels, for the return of blood. The obscurity of diagnosis, and this compensation, render vein stones of little practical interest.

## LYMPHATICS AND GLANDS.

### CHAPTER XXVIII.

#### LYMPHATITIS.—TUMOURS.

**LYMPHATITIS.—INFLAMMATION OF THE LYMPHATICS, OR ANGEIOLEUCITIS.**—*Structural conditions.*—The walls of the lymphatic vessels, when inflamed, are thickened and softened, and the surrounding cellular tissue is infiltrated with fibrinous exudation. Similar exudation mingling with the lymph within in the vessels, forms a rosy clot, obstructing their interior. *Suppuration* often ensues *limited* as an abscess, or a chain of abscesses along the course of the vessel; or as *diffuse* infiltration.

The *Symptoms* are referable both to the vessels affected, and to the part. Inflamed lymphatics present purplish-red linear streaks, tortuous and intersecting, not necessarily continuous with the source of inflammation, but running up to the neighbouring lymphatic glands, which also become involved. Erysipelatous patches frequently appear, having the same distribution, and render the islets of unaffected skin between the lymphatics more conspicuous. These red lines are hard and cord-like under the finger, and beset with a spongy swelling—the surrounding infiltration. A hot, burning pain, and tenderness on pressure, also corresponds with the course of the vessels. These symptoms are more marked when the superficial lymphatics are affected, and may be scarcely perceptible when the deeper lymphatics are principally the seat of inflammation. *Suppuration* is made known by the usual symptoms of abscess, or by those of *diffuse* suppuration, in the event of this condition prevailing. Considerable œdema of the part—possibly a whole limb—supervenes, as the vessels become occluded; and this symptomatic condition is more intense with inflammation of the deeper lymphatics. The *general* symptoms will be those of inflammatory fever, soon exchanged for prostration, or sinking into the collapse of pyæmic infection.

*Causes.*—Usually arising from some form of injury—a wound, or friction, or from the absorption of some poisonous matter, as by a dissection wound; the external and local cause of lymphatitis is frequently a trilling lesion. Some constitutional condition would appear to prevail in most cases; and this, probably, is of the erysipelatous nature.

In persons of a broken constitution, and those who are in a low state of health, inflammation of the lymphatics readily occurs, and often from scarcely perceptible external causes; the pressure of a tight boot, inducing a few reddish streaks on the inner side of the leg and thigh, with swelling and tenderness of the inguinal glands; or a slight abrasion on the hand being followed by similar inflammation of the lymphatics along the inner side of the arm extending to the axillary glands.

*Course and Terminations.*—(1) Resolution occurs not unfrequently, even in those who seem most susceptible of the disease. The reddish streaks fade away, and the œdema subsides. (2) Or, inflammation having ceased, the indurated cords may remain, with brawny swelling, for some

time. (3) Suppurative lymphatitis often leads to the formation of abscesses in the surrounding cellular texture, and possibly, sloughing. (4) Pyæmic infection is a frequent consequence, proceeding, probably, from the direct transmission of pus from the interior of the vessels.

*Treatment.*—The application of a few leeches, along the course of the vessels, may be appropriate in the absence of an erysipelatous tendency; but warm fomentations, elevation of the limb, and rest, will always be suitable, and generally prove sufficient to reduce the inflammation. Alkaline salines, and other mild depletory measures are auxiliary at an early period.

Abscesses should be opened without delay, and chronic œdema is best overcome by careful bandaging and blistering. Stimulants will soon become requisite in the course of this disease. Wine, brandy, and ammonia must be freely administered; the latter, I think, has a depressing influence, when continued for any length of time; and any stimulant supplies only a prop, to be withdrawn in proportion as nourishing food can be taken and assimilated. The treatment of pyæmia, as a consequence of lymphatitis, presents nothing peculiar.

*INFLAMMATION OF LYMPHATIC GLANDS.—ADENITIS.—Structural Conditions.*—Inflammation of the lymphatic glands differs in no important particular from that of the lymphatic vessels. Their structural resemblance explains this pathological affinity, for these glands, each consist of lymphatic vessels in the form of a network; connected by cellular tissue into a dense mass, enclosed in a cellular capsule. The lymphatics entering a gland and forming the network, are again collected into lymphatic trunks issuing from the gland. Capillary blood-vessels ramify on this network of lymphatics, and are thus brought into an intimate relation with them, anatomically and physiologically. Inflammation of the lymphatic glands is attended with some thickening of the conglomerated vessels, and infiltration of the interstitial cellular tissue with fibrinous exudation, but seldom with any permanent obstruction of the interior of the vessels. Suppuration not unfrequently takes place, forming an abscess, either centrally in the substance of the gland, or in the external and surrounding cellular texture.

The *symptoms* are simply those of ordinary inflammation; the gland becomes swollen, hard, and painful, with, perhaps, a blush of redness and heat in the superimposed integument. Induration is less notable, owing to the naturally firm consistence of the lymphatic glands; but they may acquire even a bullety hardness, as the inguinal glands in connexion with an indurated syphilitic sore. Softening may succeed in ordinary adenitis; and with suppuration, the usual symptoms of abscess supervene. Œdema commonly occurs in the part below, and proportionately as absorption becomes obstructed. The constitutional disturbance is the inflammatory type of fever, and often more acute than with inflammation of the lymphatic vessels.

*Causes.*—Usually occurring as a continuation of inflammation along the lymphatics, adenitis sometimes arises independently, from an injury, or from absorption of noxious matter, not affecting the intermediate vessels. A sprain or an ulcer may thus induce inflammation of the glands distant from the seat of either; as the inguinal glands, when the foot or shin is the source, the intervening lymphatic vessels remaining unaffected.

*Course and Terminations.*—(1) Resolution occurs in many cases of

ordinary inflammation. (2) Chronic enlargement and induration is not uncommon. (3) Suppuration may be followed by sloughing, and exposure of the glands, as reddish grey, fleshy masses, notwithstanding the destruction around them.

*Treatment.*—Leeches are seldom necessary; fomentation, rest, and relaxation by position, generally being sufficient to resolve the inflammation, aided by mild depletory measures medicinally. *Suppuration* threatening, the same treatment should be continued, and warm spongio-piline fomentations or poulticing having been assiduously employed for a few days, a bistoury should at once be introduced, and any matter set free ere burrowing has taken place. Fistulous tracks are more apt to occur with suppuration around the gland; and stimulating injections or solid nitrate of silver will then, perhaps, succeed in exciting healthy granulation so as to close these passages; failing which, they must be slit up and healed from the bottom. *Chronic* induration of the lymphatic glands is best dispersed by the occasional application of iodine paint; but, if suppuration has taken place, and perhaps circumferentially, with fistulous openings through which portions of the glandular mass protrude, it will be requisite to destroy such a mass by introducing a stick of caustic potash into its substance and turning it freely about. Thus also any induration may be dissolved. A stimulant and tonic plan of treatment must take the place of any depletory measures, during suppuration or in chronic induration; and removal of the latter may, perhaps, be aided by iodide of potassium in conjunction with this treatment.

Extirpation of lymphatic glands in a state of chronic induration becomes necessary as a last resource. I have removed such glands; in particular, a conglomerate bunch of axillary glands, which was found to consist of degenerate gland-tissue, enclosing spots of yellow, curdy pus, and cretaceous matter. Fistulous openings afterwards proved troublesome, but these closed under stimulating injections.

ENLARGEMENTS, AND TUMOURS OF LYMPHATIC GLANDS.—*Scrofulous* enlargement of these glands. (See SCROFULA, Ch. V.) *Tumours* of these glands are noticed in connexion with MORBID GROWTHS. (Ch. II.)

## BONES.

### CHAPTER XXIX.

#### FRACTURE.

*FRACTURE.*—*Structural Conditions.*—Fracture is a solution of continuity of the osseous texture, suddenly produced; and the broken ends of bone are more or less contused or lacerated by the act of breaking. Fractures differ essentially in regard to the mode of their reparation, according as they are unaccompanied, or attended, by an open wound communicating with the fracture; the one being termed *Simple*, the other *Compound*. *Complicated* Fracture is also a recognised distinction; when the injury to the bone is accompanied with injury to other parts, as important blood-vessels or nerves, an internal organ, or extends into a joint (Fig. 82), or

is accompanied with dislocation. But any such additional injury is not an essential condition, as pertaining to the pathology of Fracture.

FIG. 82.

FIG. 83.

FIG. 84.

In its extent, a fracture generally passes completely through the bone—

FIG. 85.

*complete* fracture; occasionally, it is limited to part only of the whole thickness of a bone—incomplete, or as it is sometimes aptly termed, “greenstick” fracture. (Fig. 83.)

FIG. 86.

In direction, the line of fracture may be *transverse*, *oblique*, *a*, or *longitudinal*, *b*, as compared with the axis of a long bone. (Fig. 84.) But these purely anatomical conditions are not essential distinctions.

[P. p. 191.] If there be more than two, perhaps several, fragments, the fracture is *comminuted*. (Fig. 85.) *Impacted* fracture is that condition wherein one fragment is wedged into another, the compact structure being driven into the cancellous texture. (Fig. 86.)

Generally, displacement of the fragments, in some degree, occurs with fracture; or subsequently by muscular action or the weight of the limb. Displacement may be transverse, oblique, longitudinal, angular, or rotatory, as compared with the axis of a long bone; or a depression, in the flat bones of the skull.

With fracture, the medullary web—endosteum—is torn, and completely across in most instances; the

periosteum is rarely much damaged. According to Mr. Paget's observations, the latter membrane is seldom stripped off the broken ends. Commonly, it is cleanly rent across at the same level as the fracture, and maintains its close union, having only its fibres somewhat frayed or pulled from their natural direction. Sometimes, it remains entire, even with extensive fracture; and in this case, thickening, it contributes to the security of the repair of the injury.

Any damage done to the surrounding soft textures, and the temporary extravasation of blood, are concomitants of fracture, not pertaining to the lesion itself.

*Signs.*—Fracture is attended with *mobility* of the broken portions of bone, and *cre-pitation*, a rough grating sensation, felt and heard, when the broken surfaces are gently moved in contact. Usually, the *normal outline of the limb* is altered, by the displacement of fracture and swelling, a disfigurement of *contour* which the experienced eye will frequently recognise at a glance; and there is more or less elevation or depression, also by the displacement and swelling at the *immediate seat of fracture*. (Fig. 87.) *Shortening of the limb*, in some degree, takes place when one of the long bones, as in either limb, is broken; and this resulting from the involuntary contraction of the muscles acting on the lower fragment, it takes place invariably, excepting under circumstances to be presently mentioned.

The direction in which the lower fragment is thus drawn, is upwards, and hence the shortening of the limb; but the displacement is determined by the linear action of the muscles; either in the resultant direction of their combined action in different lines, or in the direction of the stronger force of two antagonistic orders of muscles—the flexor muscles overcoming the extensors in either limb. Thus, in fracture of the humerus, betwixt its head and the insertion of the pectoralis major; this muscle chiefly, with the latissimus dorsi and teres major muscles, draws the lower portion of bone upwards, and inwards towards the thorax. With fracture of the femur in its middle third, the adductor muscles draw the lower portion upwards, and inwards behind the upper third of the femur; the approximation of the attachments of the adductors producing a certain fulness in the appearance of the upper part of the thigh, and which is more conspicuous by the shortening of the limb as compared with its fellow. When both bones of the leg are broken, the lower portions of the tibia and fibula are drawn upwards, and behind the upper fragments, by the action of the gastrocnemius and soleus as flexor muscles. Shortening of the forearm, in the opposite direction, may occur, but in a lesser degree, with fracture of the radius and ulna. Pain, and inability to use the limb, or broken bone, are *functional symp-*

FIG. 87.

toms of Fracture; but of equivocal value for an early and exact diagnosis. [P. p. 172.]

*Diagnosis.*—The pain may be insignificant at first, before swelling supervenes; and the power of motion be retained in the case of impacted fracture, or where one only of two companion bones is broken, the other acting as a splint. With fracture of the radius, in the forearm; or of the fibula, in the leg; the ulna or the tibia, thus preserves some of the motions of the limb; although the special functions of either bone may be lost. But if the functional symptoms of pain and loss of voluntary power, be well marked, they may each arise from other causes than fracture; as from dislocation, a bruise, or an attack of rheumatism, which thus far severally simulate fracture. The *physical* signs of Fracture may, *severally*, be *absent*. Mobility, in the case of impacted fracture; crepitation, if there be much displacement, or if soft tissue of any kind intervene between the fragments, or if some days have elapsed since the accident. The deformity of the limb, and the elevation or depression at the immediate seat of the injury, may be absent; as in impacted fracture, and in fracture without displacement; and these signs are less pronounced than usual, when one only of two companion bones is broken, the other resisting and supporting as a splint. Shortening also is absent in all such cases. The most difficult case is this; a fracture of one of two companion bones in the leg or forearm; and in a muscular subject, and when considerable swelling has supervened. There is no shortening and no angular deformity, no crepitation can be felt, and mobility of the broken portions is obscured by the swollen cushion of soft tissues surrounding the seat of fracture.

But if the signs of fracture be *present*, they may, *severally*, arise from other causes; with one exception—namely, mobility in the continuity of a bone. This can arise only from fracture. Crepitation may attend the play of the tendons in their sheaths, in connexion with inflammation; but the creaking, jerking crepitation thus produced, differs from the rough grating of broken bone. The altered contour of the limb, and of the part at the seat of supposed fracture, and the shortening of the limb; may arise, from a previous fracture, interstitial absorption, or other disease, of the bone, or from deformity, congenital or acquired, as rickets or mollities ossium. In the proximity of a joint, these signs may be due to dislocation; but the absence of crepitation, and of mobility, or the fact of immobility, are the turning points of the diagnosis.

It appears, then, that no physical sign taken singly, except one—mobility—is pathognomonic of fracture, and that any one sign may be absent; but all these signs taken *collectively*, determine the diagnosis. Functional symptoms, singly or combined, are insufficient; yet their concurrence further establishes the diagnosis.

*Causes, external and internal; and effects of Fracture.*—Fracture is produced, in general, by external force, suddenly applied, either to the part, or at a distance; but occasionally, it is the result of the sudden and powerful action of muscles, as in fracture of the patella, not unfrequently. *Predisposing* causes are numerous and very influential. Some relate to the functional uses of the bone; thus, the radius is liable to fracture in the manifold use of the hand; others are anatomical predisposing conditions, as the exposed position of a bone, the tibia for example; and brittleness of the osseous texture, as a condition consequent on age. Certain blood-diseases also apparently have some predisposing influence

in the production of fracture; rickets, syphilis, cancer, scrofula, and scurvy.

The lesion itself operates as an internal cause of constitutional disturbance, by producing shock in a greater or less degree, followed by reaction; or this may be accompanied by persistent shock, in the form of prostration with excitement; which is sometimes succeeded by Tetanus. [P. Ch. IX.] But simple fracture is essentially local in its effects, and does not necessarily cause any persistent constitutional disturbance.

*Repair.*—Fracture is disposed to unite by a modification of the process of primary adhesion, namely, by osseous consolidation of the bond of union; unaccompanied by inflammation, as follows:—*Inflammatory* lymph, in small quantity, is first exuded round about the seat of fracture, rendering the cellular texture more succulent, and thus producing a swelling, which, however, is partly or principally due to the blood extravasated by the injury. This mixed swelling gradually subsides; the exudation of lymph not continuing later in most cases, than the second or third day. A period of inactivity succeeds, of uncertain duration, but which, in the adult, is rarely less than one week or more than two. Then

FIG. 88.

FIG. 89.

the proper *reparative* or ossifying lymph begins to flow. A layer of this lymph is deposited between the fractured ends of bone, which, undergoing development into fibro-cellular tissue, or perchance into cartilage, and thence, in either case, into bone, restores the continuity of the fragments; forming an immediately connecting layer of bone—an “intermediate callus.” This is the *only* callus, whether the fragments be in even apposition (Fig. 88) or overlap. (Fig. 89.) The full sufficiency of an intermediate callus is beautifully illustrated in both the specimens figured; oblique fractures of the humerus—the one a fracture through the great tuberosity and part of the shaft (Museum Roy. Free Hosp.)—the other, a double fracture through the shaft (Sir A. Cooper). Neither an “external” nor an “internal” callus, therefore, is produced in the *human* subject, as was formerly supposed, excepting when the fractured limb or part is subjected to unusual motion during the process of repair, or when the original bone is diseased. Then, indeed, lymph-forming callus may be thrown out around the seat of fracture, ensheathing the fragments as with a bony clasp (Fig. 90), and formed also as a peg within the medullary canal. The lymph deposited in either of these situations speedily undergoes ossification. Around the bone, this process is chiefly or solely by outgrowth of

bone from either fractured end, and extending gradually towards the plane of the fracture, this part of the callus is last ossified. Within the medullary canal, ossification proceeds about the same time, consolidating

FIG. 90.

the cancellous tissue of the fragments, and at a later period uniting them. The walls remain still longer disunited. Either callus thus placed is formed *some time before* the intermediate lymph begins to ossify.

The new bone—wherever placed, between, around, or within—is true bone, and appears soon to acquire its proper microscopic characters. A new periosteum also is produced. At first firm, thin, and distinctly lamellar, it gradually acquires toughness and compactness of texture.

But the external and internal callus, when present, are *provisional* and *temporary*. They serve the purpose of two natural splints to retain the fractured ends in apposition while the intermediate callus is forming. When no longer requisite for this purpose, they are gradually withdrawn, the bone being fashioned off by absorption, and finally restored to nearly its original symmetry of outline. Little remains in after years to mark the scene of former injury, as if Nature, ever seeking to show her perfect work, were unwilling that any evidence of past imperfection should permanently remain on record.

Thus, then, by a modification of the reparative process of adhesion, as in an incised wound, a simple fracture is

FIG. 91.

reunited, and without regard to the particular direction of this lesion—transverse, oblique, or longitudinal—or the position of the fragments—in even apposition or overlaying; anatomical conditions or contingencies of minor consideration, pathologically and practically.

It is, indeed, most interesting to observe in corroboration of the provisional character of callus, externally and internally, that no such callus may be formed, even when the fragments are constantly subject to motion, as in *animals*. Fracture of the *furculum* or collar-bone in the common fowl, may thus unite, as shown by an appropriate and perhaps unique specimen in my possession (Fig. 91). Union of a fracture of the

thigh-bone in the same species of bird is also represented in the figure. Much thickening of the bone has occurred at the seat of fracture in this case, but no external callus, the sharp margin of the original fracture—an oblique one—being plainly seen at the line of junction by an intermediate callus, the only bond of union.

The *period* for the completion of fracture-union is uncertain. Various adverse conditions, of a persistent character, may severally tend to retard or arrest the formation of callus; thus illustrating the significance of persistent causes. [P. p. 706.] Causes predisposing to fracture, have this additional effect. Such, perhaps, are age, and certain blood-diseases—*e.g.*, rickets and mollities ossium, syphilis, cancer, scrofula, and scurvy. Other causes, not predisposing to fracture, have, perhaps, the same tendency to prevent union. Such are, febrile disturbance, erysipelas, starvation, pregnancy; and certain local conditions; as muscular action, frequent movement of a fractured limb, the direction of fracture as facilitating the recurrence of displacement, and the intervention of a piece of muscle, or dead bone, between the fragments.

The *Prognosis* of Fracture, as a lesion healing by a modification of the process of primary adhesion, is favourable. Otherwise, it will be determined by a due consideration of all those internal causes, which in their operation of retarding or arresting the formation of callus, thus perpetuates the injury.

*Treatment.*—Immediately after Fracture, the occasion for Surgical interference is urgent. The hard and rough portions of bone, subject to the action of muscles, or other movement, are apt to lacerate and bruise the surrounding textures. This state of the part is more provoked by fracture with displacement simultaneously, and when the broken ends of bone are pointed, as in oblique fracture. Hence arises increased and continued pain, spasm of the muscles, hæmorrhage and tension; or inflammation, advancing so far as to prevent the formation of reparative lymph at a subsequent period. Compound fracture may be produced, by either fragment piercing the skin. Shock also, which would have been slight and transient, is perpetuated. The rule of treatment as to time, was, and is still, I believe, with some Surgeons, to postpone any attempt to *set* the fracture at rest, until after the swelling itself—resulting from the injury—has subsided or been subdued by topical antiphlogistic measures. Some hours or even days, it is alleged,\* as a general rule, should be allowed to elapse for the realization of this purpose. The utter fallacy of this injunction, is obvious—the cause of increasing swelling still remaining in operation. Remembering, however, the period of inactivity, for a week or two, which succeeds the effusion of *inflammatory* lymph, in the first instance; the *final* adjustment of Fracture is unnecessary or useless, until about the termination of this period of non-reparation.

After Fracture, the subject of the accident should not be moved unnecessarily. If a lower limb be the seat of the fracture, it is important to wait until a suitable conveyance can be procured. A litter is best fitted to carry the person, without any jerking movement, which would inevitably damage still more the already injured soft parts. The condition of displacement with fracture, and the form of the latter, will render this consideration the more important. The production of compound fracture may thus be prevented. Hence, also, the limb should be

\* Chelius, by South.

properly secured, by tying it to its fellow, during the journey, however short, to an hospital or to home. The dress must be cautiously removed, and particularly from off the fractured limb, by ripping up the clothes.

The pathological analogy of simple Fracture to an incised Wound, as a solution of textural continuity; and the natural mode of healing in both these lesions, by a process of reparation essentially the same—namely, primary adhesion; at once suggests the two Rules of Treatment.

(1) *Reduction and Coaptation*, or the adjusted apposition of the fractured ends of bone. This condition implies a *suitable position* of the limb, to relax, as far as possible, any antagonistic muscles, which, by their spasmodic action, retain the fragments in a displaced position. It also implies some *extension* of the limb with *counter-extension* or passive resistance, sufficient only to bring the fractured ends of bone parallel, end to end; a procedure which is designated the “reduction” of Fracture. Coaptation or “setting” is then readily effected.

(2) *Maintenance of Coaptation*, during the process of reparation including the solidification of the callus. This still presupposes a suitable position to prevent re-displacement by the spasmodic action of any antagonistic muscles. But it also implies the employment of suitable retentive appliances, or *retentive apparatus*; and *both*, to ensure *rest*. This is, obviously, only the continued fulfilment, and completion, of the former rule of treatment.

Prior to the reduction of the fracture, it may be advisable to aid the vital powers in recovering from the shock of injury, by the administration of stimulants; wine, brandy, or ammonia.

Certain *exceptions* also to both the foregoing rules of treatment, are to be observed. Considering the purpose of reduction, it can be necessary only in cases of fracture, with displacement. Fracture without displacement, as when the lesion is transverse, and the ends of bone are broad and remain in contact, cannot require reduction. Such is sometimes the case in fracture of the lower part of the shaft of the femur. Then again, if one only of two companion bones, articulated together at either end, be broken, the remaining one renders any adjustment by extension and counter-extension, impossible. In fracture of the fibula, especially if high up, the tibia has this restraining effect. With fracture of the vertebræ, displacement cannot, and ought not to, be reduced. In *all* other cases, the reduction of Fracture is our first consideration in its Treatment. With displacement, angular, or rotatory, the kind of reduction is obvious. With shortening, extension and counter-extension are required.

*Reduction*.—The limb should be placed in a *suitable position*, not with the view of relaxing all the muscles, for that is impossible. No position can possibly relax “the whole set of muscles belonging to, or in connexion with, the broken bone;” as was recommended by Pott.\* On the other hand, the alleged unimportance of relaxing those muscles which resist the reduction, as taught by Desault, would be a serious error. The principle inculcated by Sharp and Pott, will ever guide the treatment of Fracture, in this respect. The limb should be *semi-flexed*, or, placed in that position which is natural to the part in a state of perfect repose. In sleep, the limbs are partly flexed, obviously, to relax the flexor muscles, which naturally overbalance the action of the extensors.

\* Works by Earle, 1790, vol. i. p. 364.

By this attitude of the limb, if complete reduction cannot be accomplished, in the first instance, the fracture may be partially reduced, and the ends of bone placed at rest; and thus in a position less hurtful to the surrounding soft textures. Indeed, in some cases, when the muscles which resist reduction, become relaxed, the ends of bone almost fall into easy apposition. They coapt, or adjust themselves into contact.

*Extension and counter-extension*, are necessary only, in so far as a suitable position is not of itself sufficient to effect reduction. So co-operative, however, is the relaxation of any resisting muscular action, that it has been, and, I believe, still continues, an open question with some Surgeons, to what *part* of the limb, the forces of extension and counter-extension should be applied? Boyer advocated the application of extension to the limb *below* the articulation with the lower fragment, and counter-extension *above* the articulation with the upper fragment. Thus, that in fracture of the leg, extension should be applied to the foot, while counter-extension fixes the thigh; in fracture of the thigh, extension should act on the leg, while counter-extension fixes the pelvis. For, it is alleged that were these opposite forces applied directly to the broken bone, the pressure of grasping the limb so near the fracture, would excite the muscles to spasmodic resistance. But the English School, has, ever since the time of Pott, urged the superior importance of flexing the limb; a position which necessitates the application of extension and counter-extension *directly*, to the broken bone; if in the leg, to the leg; if in the thigh, to the thigh.

The extending force, should not be forcible, but moderate, and moderated according to muscular resistance; equable, not jerking; and gradually increasing. Applied also, at first, in the direction of the lower fragment, the natural position of the bone is to be thus gradually regained, care being taken to restore the natural length and shape of the limb. Duly observing any deformity of the other limb, congenital or acquired; advantage may be taken of this opportunity to reduce the fractured limb to a corresponding condition, whether of length, shape, or both. Extension cannot prove effectual unless accompanied with counter-extension, equal, and opposite.

If the fracture be incomplete and the bone only bent, as happens sometimes in young children, reduction should not be accomplished all at once, but by degrees; each adjustment being secured by a suitable retentive appliance, placed so as to oppose the re-curving of the bone. In all other cases, reduction may be accomplished according to the directions just given.

*Coaptation* of the fractured ends of bone is effected by the act of reduction in some cases. Muscular resistance having been overcome by a proper position of the limb, the ends of bone readily come together; or they are easily adjusted by a little gentle manipulation. Any rough handling would further damage the soft textures round about the fracture. The ends of bone being brought parallel, their contact is announced by crepitation. This sensation and audible sign, also assures the Surgeon that no portion of soft-texture, as muscle, intervenes between the fragments; a condition which would impede or prevent their union. Adequate extension and counter-extension must, of course, be continued, during the application of any retentive measures; and in some cases subsequently, as will presently appear.

To maintain *Coaptation*—to retain the fractured ends of bone in

adjusted contact—position must still be observed for the relaxation of any antagonistic muscles which would cause re-displacement. Flexure of the limb, in various degrees, according to circumstances, is generally most suitable; especially in fracture near a joint, where ankylosis appears inevitable. Splints, of wood, pasteboard, leather, gutta-percha, or iron, and bandages; constitute the retentive appliances generally employed.

*Splints*, made of wood, are suitable in fractures of the lower extremities, where more strength of material is required; and the tin trough, or Liston's modification of McIntyre's splint is well adapted for fracture of the leg. Pasteboard, leather, or gutta-percha splints, are adapted for fractures of the upper extremities.

Splints are not always indispensable. In one or two fractures, coaptation can be maintained effectually by position and bandages alone; for example, fracture of the clavicle. *Two* companion splints are generally requisite, one on either side of the fractured limb. Each should be broad enough to cover and protect the whole depth of the limb, but not to double over it. If too narrow, or too broad, the bandage applied will either exercise undue pressure, or not support the unprotected soft textures, between the splints. In point of length, the splints should extend over and beyond the joint at either extremity of the broken bone; so as to fix it steadily, not by pressure on the seat of fracture, but by securing both these joints. With fracture of the thigh, the hip and knee; with fracture of the leg, the knee and ankle; are to be thus secured: "The true and proper use of splints," observes Pott, "is to preserve steadiness in the *whole* limb, without compressing the fracture at all." Hence the above rule of practice, and which he first inculcated. Splints should be comfortably *padded* with some light yielding material, as tow, or cotton-wool; and more particularly over prominences of bone, to prevent sloughing. Over the seat of fracture, any pressure is especially apt to peril the intervening soft textures, already damaged; while to forcibly subdue a *rising end* of bone by pressure, will surely induce sloughing, and rarely prove mechanically successful. Its replacement is best effected by removing the cause of such projection. Alteration of position, therefore, will be necessary to relax the muscles which are acting on the upper fragment, while the lower one should be adequately supported underneath. In certain fractures, this rising of either fragment is only apparent, and really due to the natural shape of the bone, as the arching forward of the clavicle; or, it may be an acquired deformity, as convexity of the tibia, from rickets.

The splints having been well adjusted, they are secured in position by a *bandage*, evenly applied round the limb from below upwards, and with just sufficient pressure for *this* purpose. No further restraint is required, excepting in the case of a maniac or a delirious person. If the fracture be subcutaneous, and either fragment threaten to protrude through the integuments; that portion of the limb may be left uncovered, or the splints lightly retained by a separate roller which can be readily removed without unbandaging the limb. No bandage need be applied *underneath* the splints, as was formerly practised, and is even now-a-days advocated by some Surgeons, with the view of preventing œdema. A bandage so placed becomes tense, as swelling inevitably ensues, and is thus apt to cause strangulation and gangrene. This result may, indeed, occur imperceptibly, and gangrene overspread the whole limb without any notable constitutional disturbance to arouse suspicion. Hence, also, in

applying the bandage around the splints, in the first instance, some degree of yielding should be allowed for the supervention of swelling, the splints being bound with sufficient firmness only to prevent displacement of the fracture. The *roller-bandage* is commonly used, and it is available where the limb can be moved without displacing the fracture. Rather than risk displacement, the *tailed-bandage* of Scultetus is a convenient substitute. It consists of a series of short strips of bandage laid transversely under the limb. Commencing below, each strip is drawn round the limb, so as to partially overlay and secure the next in succession. This contrivance forms an adequately firm bandage, like the common roller, extending uninterruptedly along the limb; but neither allow of tightening and relaxation, here and there, as occasion may require. The *looped-bandage* is specially adapted for this purpose, and without moving the limb. Double strips of bandage are placed transversely under the limb, at short intervals apart. One end of each is passed through the looped extremity, and being drawn sufficiently tight, is secured by tying it to the other free end. The splints are thus fixed by a series of ligatures, any one of which can be braced or loosened at pleasure, without altering the whole.

Extension must be maintained, in *some* cases, *after* the application of retentive appliances; and this, perhaps, cannot be accomplished without some *special* mechanical contrivance in the splints, or otherwise. In fracture of the femur, displacement is apt to recur. Desault's or Liston's long extending splint, with a straight position of the limb, overcomes any such tendency; extension being maintained by that portion of the bandage which passes round the foot-end of the splint, and counter-extension by a perineal band. This mode of treatment is here more advantageous than that of relaxing the muscles, by semi-flexing the limb and laying it on its outer side, as was proposed and practised by Pott. The general

FIG. 92.

principles of treatment in regard to the maintenance of coaptation by retentive appliances, may be illustrated by the treatment of fractured femur, as here represented. (Fig. 92.) Extension may be aided by a *weight* slung from the extremity of the limb; as from the foot, in fracture of the femur attended with unusual tendency to displacement. But a heavy weight is unnecessary; three, four, or five pounds weight, will suffice to tire the muscles and overcome their resistance. Extension is maintained, in certain instances of fracture, by means of an adjoining *bone*, used as a lever. In fractured clavicle, the humerus is utilized; an axillary pad being the fulcrum. Counter-extension is also secured, occa-

sionally, by means of an adjoining bone as the resting point. In fractured fibula, the head of the tibia is made the fixed point for Dupuytren's splint.

A suitable, yet simple, retentive apparatus, of splints and bandages, having been adjusted; the limb is rested and supported in a moderately *elevated position* to relieve any tendency to congestion, provided such elevation be compatible with that position whereby the muscles are most relaxed. In fractures of either lower extremity, where the patient remains in bed, a firm mattress is required to support the limb evenly and equably throughout its extent. If the fractured *part* be unsupported, it bends somewhat by its own weight, and displacement with eventual deformity will ensue. If either *end* of the limb be allowed to sink, there is the same tendency. Moreover, an *even* support to the whole limb, is the best safeguard against sloughing from undue pressure on any one point. The weight of bed-clothes, if tending to disturb the fracture, may be removed by a *cradle*. Spasmodic action of the muscles continues, in most cases, only for the first few days after the fracture has been set, during which period, therefore, displacement is most apt to recur; but, as the process of reparation scarcely begins before ten days or more—the “brooding-time” has elapsed, the *final* adjustment of any displacement is comparatively unimportant until *then*.

It is here, especially, in point of *time*, and subsequently, that the guidance of Pathology is superior to Empiricism, in regulating the interference requisite during the course of Fracture-union.

The reparative lymph forms a soft callus, fibro-cellular or cartilaginous, which remains *pliant* for some days or weeks; and, as proceeding from the living bone, it is self-constructive, and adapting in its supply; differing in all these provisions from the sudden and passive setting of any inorganic concrete or cement, and which is without increment, in any artificial mode of adhesion. During the process of reparation, therefore, the pathological Surgeon is ever watchful, never meddlesome, in his regard to the correct coaptation of the fragments, and the consequent length and shape of the limb. *Absolute* rest of the fractured part is not essential to union without displacement; and this suggestion of pathology regulates the degree of security requisite in any form of artificially retentive apparatus. Every *trivial* displacement, also, of the splints and bandages, need not be readjusted. If, however, the bandages slacken, they must be reapplied; if the retentive appliances get disarranged, they must be replaced. On the other hand, if pressure has become undue at any part, whether by swelling of the flesh, or setting of the padding, that part should forthwith be relieved; ever remembering that the Surgical purpose of any “retentive apparatus,” is not to fix the limb in a vice; but only so as by securing rest, to gain time for the injured part to itself undergo the process of reparation.

If, therefore, spasmodic muscular-action still recurs, from time to time, and threatens to frustrate the healing operation of Nature; the rebellious muscles should be coaxed if possible—not coerced—by any acceptable alteration of position; and quieted by the administration of sedative medicines, of which, opium and the tincture of digitalis, are, perhaps, the most antispasmodic. Tenotomy has been proposed, as a last resource, in the most obstinate cases; and division of the tendo-Achillis has been practised with success, in fractures of the leg.

At length the proper time arrives, when splints and bandages may be

exchanged for an "immovable apparatus." When all chance of swelling has passed, spasm has ceased, and soft union is established, *then* only is the "starched" bandage *safe* and *advantageous*. At an earlier period, the unyielding nature of a solid casement, would not allow for *any* alteration whatever, in the size of the limb. As swelling inevitably supervenes, the immovable apparatus tightens, even to strangulation, and when the limb shrinks, it becomes as much loosened; thus entailing an almost daily entire reapplication of the apparatus, at that period of fracture. The unyielding nature of the starched bandage is offensive also to the muscles about the fracture, at a time when they are most irritable and susceptible of spasm. Professor Erichsen—I observe—advocates the use of a starched bandage at almost the *earliest* possible period after fracture, urging its safety and advantage, chiefly on these grounds; that it takes the shape of the limb "accurately and readily," and retains this shape by virtue of its "solidity."\* But these very characters of the starched bandage, are, in my opinion, the most obvious and valid objections to its application at that time. I am accustomed thus to fix the limb immovably, only when it no longer needs watchful supervision; and such apparently was Erichsen's rule of practice formerly.

The construction of the starched bandage, and other kinds of immovable apparatus, for fracture, should be well understood. By no means a recent invention; albumen and flour mixed, were used by Cowper, to stiffen fracture-bandages. Powdered chalk was preferred by Lawrence. Dextrine, by Velpeau. Gum arabic, with whiting, is the mixture recommended by Smee. Gum-shellac with glue, has also been employed. Plaster-of-Paris, by Mathiesen and Van der Loo of Holland; also by Kluge of Berlin, and Pirogoff of St. Petersburg. Starch was introduced by Baron Seutin, in 1834. A layer of cotton wool having been wrapped round the limb, and more thickly over bony prominences, short splints of softened pasteboard are adjusted around the seat of fracture; and, over all, a roller is applied in the ordinary manner, beginning from below upwards. A second roller is then applied, and the whole limb, thus encased, is smeared over with thick starch which is worked in with the hands. A third roller may be used, if necessary, as additional security. The casement formed, dries firmly in a day or two (Fig. 93). Plaster-of-Paris has only one mechanical advantage; it dries, and sets in a few minutes. This forms the most rigidly immovable apparatus, and is especially serviceable when the patient must undergo a journey. Supported by a starched bandage, the patient can move about at a much earlier period than otherwise; a great

FIG. 93.

\* Science and Art of Surgery.

advantage in relation to the general health, as compared with the prolonged confinement endured in the Treatment of Fracture formerly.

No *medicinal* treatment or scarcely any of a constitutional character is, usually, required in the course of simple Fracture. The shock of injury having passed off, the healing process goes on without apparently troubling the general functions of the body; and they, in turn, take little or no notice of the local process. If all the local circumstances of the part itself be conducive to healing, and the individual be in good constitutional health, at the time of the accident; it is then as natural for a fractured bone to heal and restore itself, as to maintain its own healthy integrity of structure by nutrition. Diet should be adapted to the altered hygienic condition of the individual, now disabled for business or pleasure; and, more particularly it should be proportioned to the wants of reparation. At first, therefore, moderate and comparatively innutritious, the diet must soon be more liberal and nutritious. Mild aperients, just to regulate the bowels, are needed not unfrequently, when the patient is confined to bed; but active purgatives are, by their action, apt to occasion disturbance of the fractured part, and so peril the process of union.

In due time—a period varying considerably according to the age and health of the individual—any retentive appliance may be *finally* removed with safety. The fracture must then be gently tried, to test its solidity, by passive motion of the limb. If firm union has taken place, the functions of the limb should be as tentatively resumed. In fracture of the lower extremity, this trial of power should be made *very* gradually; for if worked too soon, the limb shortens under the weight of the body, and permanent crippling is the result. Œdema, in some degree, is inevitable, when first the limb is allowed to be free and pendant. Gentle frictions will aid in restoring the circulation; and a lightly applied bandage gives support to the flesh, as yet flabby. Prolonged confinement, however, would tend to permanently waste and weaken the limb.

Thus—as in the management of an incised wound—the artificial support of a fracture is gradually withdrawn, and the limb allowed to resume its functions as gradually; until at length unaided Nature can stand alone.

**COMPOUND FRACTURE.**—*Structural Condition, and Diagnostic Characters.*—Compound Fracture is, essentially, Fracture, with a wound in the skin communicating; thus exposing the seat of fracture, however indirectly, to the action of the air. The structural disorganization, as regards the state of the bone, is the same as in simple fracture: but compound fracture is usually accompanied with more severe contusion or laceration of the surrounding soft textures. This condition, coupled with that of the aperture externally, which is also contused or lacerated; together form a Contused or Lacerated Wound, connected with, and around, a Fracture.

The *Signs* of this injury are the same as those of simple fracture, with the additional and distinctive character of an external irregular wound. Therefore, both the condition and characters are those of simple Fracture, *plus* those of contused or lacerated Wound.

*Causes, and Effects of Compound Fracture.*—Here again, the pathological history is that of simple fracture, with certain peculiarities superadded. External violence is generally the cause of the wound in the skin and subjacent soft parts, as well as of the connected fracture; which may then be regarded as produced by an extension of the injury from *without*.

Or, the fractured bone may itself penetrate to the surface and through the skin; the wound then being an extension of the injury from *within*. In the one case, the force is applied directly to the seat of fracture, and the injury is more a contusion; in the other case, the force is applied indirectly, to the bone at some distance off, and the injury is more a laceration, and less extensive. In both cases, the contused or lacerated textures are damaged beyond the apparent extent of injury; and the Shock to the nervous system is more severe than with simple fracture, owing to the greater damage to the soft parts, including nerves. Tetanus is, perhaps, more apt to supervene than after a contused or lacerated wound alone, and especially if the compound fracture be oblique, and movable among nerves and muscles [P. p. 441]. The textures injured, being in a state of disintegration, die, at least to some extent around; if the wound be allowed to remain open. This purely *traumatic* gangrene is the same as that caused by a contused or lacerated wound. Limited, therefore, to the part injured, and defined, eventually, by sloughing, or by a line of demarcation between the living and dead textures; the gangrene is immediate also, if the injury itself be severe.

*Course, and Termination.*—Inflammation supervenes, followed by suppuration, often profuse, and partial sloughing; or by gangrene, on a larger scale. Either degree of mortification, arising from inflammation, is limited to the seat of injury. By this process, however, a fracture which originally was simple, may become compound, in some cases. Ultimately, the tendency of compound fracture, when reduced, is to undergo reparation; union of the fragments taking place, either through the medium of fibrous texture, an imperfect support, or through a bony callus, with firm consolidation. Ununited fracture, and false-joint, will be hereafter considered. The wound in the soft textures closes up and heals by suppurative granulation and cicatrization. *Spreading* gangrene—due to some morbid condition of the blood—supervenes on compound fracture, only as an occasional contingency; and its phenomena have been already described in connexion with the course of contused and lacerated wounds.

The *Prognosis* of Compound Fracture, as gathered from a due consideration of the natural course and tendency of this lesion, is far less favourable than that of simple Fracture. An *open* wound, communicating with the seat of fracture, as compared with subcutaneous laceration of the soft parts, is one unfavourable ground of prognostic distinction. Scarcely less so, is the *greater extent* of their laceration, usually in compound Fracture; especially if produced by direct violence. [P. p. 723.] *Spreading* gangrene is an adventitious condition, yet a most unfavourable one, as implying the co-operation of a constitutional cause. [P. p. 737.]

*Treatment.*—The same rules of treatment are applicable as for simple fracture; but, certain particulars, having reference to the special pathology of compound fracture, are peculiar to its treatment.

*Reduction* of the displacement may present special difficulties. Thus, if one or both ends of bone *protrude*; whether this condition has arisen passively, simply by the original force of the fracture; or subsequently, by the sheer weight and position of the limb, or possibly by rough handling—the displacement can be reduced by sufficient extension of the limb. When, however, such displacement is due rather to muscular contraction and spasm, acting especially on the lower fragment which is thus drawn upward; enlargement of the wound, by incision, is preferable to forcible extension; and this proceeding is the more urgent also, in

proportion to the circumferential swelling, from hæmorrhage or serous effusion. With increasing tension, the protruded portion of bone becomes tightly embraced by the aperture in the integuments, through which it has passed; a condition not unfrequently witnessed in compound fracture of the tibia, and which obviously suggests the propriety of enlarging the aperture to free the bone. An exceptional case sometimes occurs; when protrusion arises from *deformity* of the bone, as in rickets. Excision of a portion of the bone may then be necessary to reduce the displacement. Union, firm and permanent union, will probably take place; with or without, the reproduction of new bone as an intermediate callus. The limb, accordingly, is ultimately restored to its original length, or remains proportionately shorter than its fellow. In one such case, where the tibia was arched forward, in consequence of rickets, I removed two inches of that bone, an inch from either fractured end; and the result was highly satisfactory. [P. p. 773.] *Splinters* of bone have special significance in relation to the treatment of compound fracture, there being an open wound communicating. If only partially detached, any such portion of bone may retain its vitality and regain its connexion. But if completely detached, the fragment is obviously a foreign body, and should be removed accordingly; a proceeding the more imperative, when any such fragment intervenes between the fractured ends of bone; thus opposing their reduction and intercepting their subsequent apposition, and the process of reparative union. In any case, where a considerable portion of bone is removed, in compound fracture, whether owing to protrusion, deformity, or splintering; care should be taken, in maintaining reduction, that the interval between the ends of bone be not equal to the portion removed; lest, an inadequate length of callus being produced, imperfect union should be the result.

*The Wound.*—Reduction-difficulties having been overcome, and the limb retained in position by suitable splints, well padded and protected by oiled silk from the soaking of any discharge issuing from the wound; then comes the treatment peculiar to *compound* fracture—the treatment of the wound, and state of the soft parts involved. The *primary* indication is to close the wound, with the view of soliciting its union by adhesion, and thus convert the fracture into a simple one. For this purpose, a pad of lint, soaked in blood from the wound, as formerly practised, or better, simply wet lint, or soaked in carbolic-acid solution, should be applied over and around the wound, so as entirely to exclude the air.

Considering the great difference, in safety and time, between primary adhesion and the process of suppurative granulation; assuredly the former mode of reparation should be first solicited in *all* cases. In some compound fractures, with comparatively little laceration of the soft textures and of the aperture externally, as when produced indirectly, by protrusion of the bone; the wound being closed and protected from the air, heals by adhesion in a few days, and the subsequent progress of the case is that of simple Fracture. In other cases, with confusion of the wound and sub-jacent textures, this mode of healing may be *tried*, in the *first* instance; but abandoned immediately effusion and tension supervene in any such degree as clearly indicates the necessity for a free discharge of clots, and of matter during the course of suppuration. *Early* solicitation of primary adhesion, and *timely* abandonment of the attempt, in favour of suppuration, as soon as this event occurs or is inevitable; constitute a compromise, which overrules any objection as to the *probable* failure of the one

and the supervention of the other. If the attempt prove successful, the advantage is gained of then having to deal with only a *simple* Fracture.

*Suppuration*, or *Gangrene*, having supervened, the treatment should respond to these consequences of Inflammation. Firstly, as regards *local* measures. With progressive suppuration, pus may be diffused and accumulate, without much if any tendency to point; then, *early*, *free*, and *dependent incisions* are necessary, for the easy vent of matter as it forms, and to relieve tension. Otherwise, the pent-up matter, working its way about the seat of fracture and among the textures around, dissects and detaches the bone, periosteum, muscles, nerves, and vessels; and thus destroying their continuity, the fracture remains ununited, and the parts around become saturated and soddened; in short, an irreparably disorganized limb is the result. Consequently, at a later period, incision may be necessary to remove any portion of dead bone, whether as an *exfoliation* or a *sequestrum*. Compresses of lint, properly applied, will do much to prevent the burrowing of matter; and the pad of wet lint, or lint soaked in blood, which closed the wound in the first instance, may now be advantageously exchanged for a poultice, or piece of wet spongopiline, as a cleaner application, to promote the discharge, for a time. But this should be succeeded by light water-dressing, or with carbolic acid solution, when the continuance of warmth with moisture would only sodden and relax, and when the wound is granulating. The same rule holds good whatever number of incisions may have been made; the spongopiline, and subsequently, water-dressings, varying according to the requirements of the case. Secondly, as regards *hygienic* and *medical* treatment for the constitutional disturbances consequent on Suppuration and Gangrene, respectively. Pathology, at present, guides less than experience in this direction. The interpretation of hectic, and of gangrenous typhoid fever, is considered under Inflammation, p. 55, and Gangrene, p. 149.

*Hectic fever* and exhaustion, consequent on prolonged and per chance profuse suppurative discharge, are best relieved by a diet, consisting principally of animal food, in which albuminoid matters prevail, with wine, beer, or spirits, according to the patient's previous habits. In short, what is termed a nourishing and stimulating diet, is most efficacious; the quantity of food being regulated by the digestive power of the individual, and the stimulants proportionate to his previous habits and present exhaustion. Tonics, in the shape of quinine and the diluted nitro-muriatic acid, or other mineral acid; are to be regarded only as serviceable adjuncts. Sleep must be procured by an opiate nightly, when necessary; and restlessness allayed by maintaining the influence of opium, slightly, day by day, until the strength is somewhat restored. Careful regulation of the alvine evacuations is a most important injunction throughout the course of hectic fever; any approach to constipation increasing the general irritability. It may, however, often become necessary to check, if possible, the tendency eventually to diarrhœa. The hygienic and medical treatment for the *typhoid fever* arising from gangrene or sloughing, is substantially the same as that for hectic fever. But this also will be more properly resumed with the general pathology of Gangrene.

The foregoing rules of treatment presuppose the preservation of the limb, in compound fracture, as well as the obvious indication of preserving life.

*Amputation.*—The question of amputation, depends upon the super-

vention of profuse suppuration with perhaps necrosis, or of traumatic gangrene; in either way, the limb is *irreparably* disorganized, and life thereby endangered.

1. When the *whole substance* of a limb is involved by the injury of compound fracture, either or both results are *inevitable*; and there is no alternative but *primary*, or immediate, amputation.

Such was the condition in a case of *compound and comminuted fracture* of the *tibia*, just below the anterior tubercle, with *fracture* of the *fibula*, one inch below the head of that bone (Fig. 94, showing appearances on removal of integuments). But there was also (as represented) extensive *laceration* of the *muscles*, particularly of the *tibialis anticus* muscle, which was torn across and thrown inwards over the *tibia*; the *anterior tibial artery* was torn through (as indicated by the lower pin in the figure), but the corresponding nerve and the *musculo-cutaneous nerve* (seen above) were entire. Here, then, in addition to the worst kind of fracture of

FIG. 94.

both bones, the conditions were present of inevitably profuse suppuration, by extensive laceration of the muscles, and of impending gangrene, by rupture of the anterior main artery. This injury was caused by contusion of the leg between a brewer's dray and a post, and I may add, therefore, another lesion had occurred—*extensive detachment* of the *skin* from the deep fascia of the limb, the superficial, cellular, or subcutaneous fascia being infiltrated with blood. It corresponded to the large sheath of integument thrown back in the figure. This condition I have found also

in the dissection of many other limbs severely injured by direct violence. It may be present without any wound in the skin, or discoloration at first, and it may exist far beyond the apparent seat of injury, thus misleading as to the *part* proper for amputation. The characteristic external appearance of this *typical* example of bad compound fracture is represented in the adjoining figure of the limb, as seen within a quarter of an hour after the accident. The swelling, of considerable size, corresponded to the lacerated and blood-engorged extensor muscles, and their displacement inwards over the tibia. Four apertures in the skin, the two upper communicating directly with the fracture, complete the picture.

2. When, however, the extent of damage is itself *partial*, the supervention of profuse suppuration or gangrene is but *proportionately probable*; the limb is *not* inevitably lost, nor the life surely perilled. Accordingly, the postponement of amputation until the *actual supervention* of either or both these local conditions, in other words, *secondary* amputation, should be the rule observed, in order to give the limb *its* chance of preservation; the safety of life being provided for, by *timely* amputation, under these circumstances.

The question of amputation, and as primarily or secondarily, is determined by these two pathological considerations.

Certain rules, however, as to the urgency of amputation are laid down in surgical works, according to the *extent* of injury to the vessels, nerves, &c. Any such pathologico-anatomical conditions have significance, only in proportion to the certainty or probability of profuse suppuration or gangrene supervening. But observations of the course and tendency of compound fracture, in different doubtful cases, have not hitherto been sufficiently accurate and ample, to establish any such absolute rules of practice with respect to amputation; and less so when the necessarily unknown capabilities of the reparative power in different individuals, are also taken into account. No Surgeon can positively determine whether amputation should be performed in a doubtful case; guided by this or that extent of injury, and in this or that individual. Misled by *à priori* considerations suggested by the pathologico-anatomical conditions of compound fracture, clinical observation is precluded; and thus many limbs are probably sacrificed surgically, which otherwise might be saved, if the treatment were determined by watching the actual course and tendency of the case; in other words, by observing the pathology of the particular form of injury, and as subject to the reparative power of the individual. Not one of the conditions of compound fracture, alluded to, are found to be invariably followed by profuse suppuration or gangrene; not one of the considerations commonly urged in surgical works, as to the necessity for primary amputation, are infallible. If then, *exceptional* cases are discovered by the advancing study of pathology; in how many more cases, might limbs, hitherto sacrificed surgically, have been saved, and be preserved in future?

With such qualifications, the following forms of compound fracture may be condemned to primary amputation:—

(1) Fractures, in which the wound is the consequence of the violence that breaks the bone, and in which there is *much laceration of, and extravasation into, the soft parts*; more particularly if the integuments be stripped off, portions of the muscular bellies protrude, and the planes of cellular tissue between the great muscles of the limb be torn up and infiltrated with blood. Injuries of this description occurring in the *lower*

extremity always require amputation. The danger to the patient increases not only in proportion to the amount of comminution of the bones and of injury to the soft parts, but also in the exact ratio of the *proximity* of the injury to the *trunk*. Thus, amputation of the thigh for bad compound fracture of the leg, though a very serious operation, is sufficiently successful; but when the femur itself is badly fractured and amputation of the thigh high up is required, recovery can indeed but seldom be expected. A bad compound fracture of the thigh, high up, may almost be looked upon as a fatal accident. In the arm, such accidents are not so serious, and admit of the member being saved, unless the bones be greatly comminuted.

(2) When one of the *larger arteries of the limb has been wounded* by the violence that occasions the fracture, or has been lacerated by the broken bone itself, there may be copious arterial hæmorrhage externally, as well as extravasation into the general cellular tissue of the limb. These cases most commonly require immediate amputation; care being taken, that hæmorrhage be temporarily arrested by the application of a tourniquet to the main artery, and an elevated position of the limb.

(3) *Comminution or splintering* of the broken bone, with compound fracture of the femur, may generally be regarded as a case for immediate amputation; except when occurring in the upper third, which is generally fatal; or when the comminution is trivial, the splinters large, lying in the axis of the bone, and the subject young—favourable circumstances which render amputation unnecessary. In the arm, forearm, and hand, and in the leg, provided the knee or ankle-joint be not involved, much may be done in the way of removing splinters of detached bone, and in sawing off smoothly the rugged ends of the fixed fragments.

It is a question for further observation to determine, how far *excision* may surpass amputation in all *localized* complications of compound fracture.

(4) *Wound of a large joint*, with compound fracture, more especially if there be crushing or splintering of the bones which enter into its formation, with extensive laceration of the soft parts, is one of the most serious injuries that can be inflicted on a limb; and, when occurring in the *lower* extremity, it may be looked upon as a case for amputation—unless it be the hip-joint that is so damaged, when there will generally be so much injury inflicted on the pelvic bones and their contained viscera, as to preclude the performance of any operation. When the elbow or the shoulder-joint is the seat of compound comminuted fracture, with extensive injury of the soft parts, and possibly laceration of contiguous nerves or large blood-vessels, the case is one for immediate amputation. But, if the injury be localized to the bones, the soft parts being in a favourable state, *excision* of the articulation may advantageously be practised.

(5) *A simple fracture high up, with a bad compound fracture low down in a limb*, is a complication affecting the *part* to be chosen for amputation. This will depend on the condition of the soft parts *between* the two injuries. If sufficiently sound for healthy flaps, that part should be selected; if otherwise, the part immediately above the simple fracture must be the seat of amputation.

(6) *A dislocation high up, with a bad compound fracture low down*, is a similar complication as to the *part* for amputation. If a simple dislocation, it should be reduced, and amputation then performed as low down as may be compatible with sound flaps, above the compound frac-

ture. If the dislocation be compound, amputation at, or above, that joint is unavoidable.

*Spreading* traumatic gangrene, arising from compound fracture, has the same relation to amputation, as in the case of contused or lacerated wound. The rule of treatment should be; removal of the exciting cause by amputation of the limb, without delay, and at some height above the seat of fracture—no line of demarcation forming in spreading gangrene, to indicate the time and part for amputation.

COMPLICATED FRACTURE.—These injuries follow naturally in the order of description after compound Fracture, which is a complication relatively to the simple form of this injury. But the complications here referred to are *any additional* injury or injuries which may be received simultaneously with Fracture, whether itself simple or compound; and *any morbid condition*, local or constitutional, which may be connected with either lesion as predisposing to its recurrence, or as affecting the process of its repair. Any such additional injury or morbid state complicates the whole pathology of Fracture, enlarging the consideration of its structural conditions, and diagnostic characters; internal causes, course, and results. The pathological indications of treatment are more numerous, accordingly.

Fracture may be complicated by association with *injury* to a *large artery* or *nerve*, by extensive laceration of the *muscles*, by extending into a *joint*, or by an accompanying *dislocation*. It may be associated also with injury to some special part or *internal organ*; as fracture of the pelvis implicating the bladder, of the ribs wounding the lung or pericardium, or of the skull injuring the brain. Then again, Fracture may be complicated by association with some *morbid condition*, local or constitutional. Thus, certain blood-diseases predispose to fracture, and retard or arrest the formation of callus. Rickets, syphilis,\* cancer,† scrofula, and scurvy, have severally this twofold effect; while febrile disturbance, erysipelas, starvation,‡ and perhaps pregnancy,§ severally tend to prevent union. Opinions are, however, divided, respecting the preventive influence of, at least, some of these conditions; and the references given will afford further information.

Some of the foregoing complications of Fracture may be regarded as combinations of other forms of *injury* therewith, and which have been *already* considered, in connexion with compound fracture; as injury of a large blood-vessel with fracture, fracture with dislocation, &c.; others pertain to *special* pathology—*e.g.*, injury of the brain, or other internal organ, with fracture.

Of *morbid* conditions; the local are but *manifestations* of the constitutional—*i.e.*, of the blood-diseases, to which I have just adverted; and these will be considered in relation to Ununited Fracture.

*Treatment*.—Two pathological considerations are of general practical importance and applicability. 1stly. Is the complication any *morbid condition* or *conditions* in operation, locally or constitutionally; which, as internal causes predisposing to Fracture, perpetuate the injury—whether

‡ American Journ. Med. Sciences, Jan. 1842. Monograph by G. W. Norris.

§ Ibid. See also this monograph for complete information and references on all other causes of "Non-Union after Fracture."

simple or compound—or retard the natural process of repair? In this case, the treatment must be entirely subject to such one or more *causative* conditions. 2ndly. Is the complication any *injury* or *injuries*, *additional* to Fracture? In this case, the treatment of the *fracture* may be of entirely subordinate importance, even although it be, as in many such cases, severely Compound.

**DISEASED CALLUS, AND DEFORMED UNION.**—These conditions represent the unfavourable terminations of United Fracture.

The whole pathology of Diseased Callus is that of Diseases of Bone in general; but they may severally be associated with Deformed Union after Fracture.

**Structural Conditions.**—Deformed Union of Fracture appears in various shapes, according to the relative position of the fragments. (a)

FIG. 95.

Union with displacement; angular, rotatory, transverse, or lateral, with overlapping of the fragments, and oblique or longitudinal displacements. (Fig. 95.) (b) Union of two adjoining parallel bones, as the radius and ulna, the tibia and fibula, or two adjacent ribs.

**Diagnostic Signs.**—These various conditions of deformed union present obviously characteristic appearances; but they resemble the appearances produced by corresponding displacements in Fracture, without union. Absence of mobility will always be distinctive of deformed union.

**Causes, and Effects of Deformity.**

—The *external* causes of deformed union after Fracture, may be any circumstances which occasion displacement of the fragments. Thus, unsuitable retentive appliances, or their unsuitable application, will have this effect; so also, rough-handling of the part, during the process of repair.

*Internal* causes comprise; muscular action displacing the fragments; and *diseased* conditions of the callus; as exuberant callus, resulting from inflammation affecting it during, or after, its formation.

The *effects* of deformed union of Fracture, are *mechanical*. If occurring in the neighbourhood of a joint, its action will be impaired. If in the shaft of a long bone, as the femur, ineffectual power is experienced, and in various ways, according to the direction of displacement. Thus, shortening of the limb occasions lameness. If two companion bones are conjoined, serious loss of function may be the result; as loss of pronation and supination of the forearm by union of the radius and ulna. Or such union may be unimportant; as in the case of the tibia and fibula.

**Terminations.**—In respect to the process of union, the vital history of deformed-union presents nothing peculiar. The recognition of two stages

in the process is, however, of practical importance; recent or *incomplete* ossification of the callus, and old-standing or *complete* union.

*Treatment.*—(a) *Recent* union, with displacement, suggests the propriety of endeavouring to rectify the deformity *gradually*. *Extension* and compression may be applied; either by manipulation, from time to time, and the interim application of a suitable retentive apparatus, or by means of some contrivance to slowly reduce the displacement. Either should be worn as long as occasion requires; say, from 3 to 5 weeks. Successful results have been obtained in numerous fractures after union of some duration; as 25, 29, 59 days; and possibly, after 4 or 5 months. In the event of a *more* unyielding callus, although still of recent formation; *refracture* becomes necessary, but this must still be done gradually. It may be accomplished, in like manner—by manipulation, or by the application of a screw-press; in either way, the object being, to break the callus, under the influence of chloroform, and to reset the bone in its natural axis and position. The extreme period of union when this procedure can be safely resorted to, is determined principally, by the *degree* of consolidation which may have taken place. *Experience* has sanctioned different periods of limitation. Thus, the 24th week, is the extreme limit advisable, according to Osterlen. A little longer was conceded by Bosch, perhaps 6 or 6½ months. Mr. Skey, however, in one case refractured the leg of a boy, æt. fifteen, 13 months after the original fracture.

(b) *Complete* osseous-union, can only be overcome by a *cutting* operation. The callus having been laid bare, it may be *divided*—the operation of *section*—by a small saw or bone-forceps; or *excision* of the callus may be necessary, particularly if it be exuberant. The ends of bone are then to be readjusted aright, and the case treated as compound fracture. But the very fact of this condition resulting from the operation, coupled with the inherent peril of the operation itself; render it one not lightly to be entertained. To say that by an incision the callus is reached, does not convey a true idea of the operative difficulties subsequently experienced, owing to various *pathological* conditions of the callus, and of the parts around.

For the inter-union of two *contiguous* bones, accompanied with serious loss of functional utility, as pronation and supination in the forearm; division of the callus is more imperatively necessary, if refracture cannot be accomplished. But with union of the tibia and fibula, either, and indeed any operative proceeding is generally unimportant; and as regards the junction of two ribs, is obviously impracticable.

UNUNITED FRACTURE, AND FALSE-JOINT.—DISUNITED FRACTURE.—*Structural Conditions.*—Four varieties of Ununited Fracture are recognised; two of which may be regarded as stages of non-union, and two, of false-joint; in either case, proceeding from incomplete to complete. They thus form a continued series of structural conditions, from imperfect union to perfect articulation. (a) The fractured ends of a bone may be united by an ensheathing *cartilaginous* callus; which, however, fails to undergo ossification. This condition is known by partial mobility of the part when handled, and the limb is proportionately useless. (b) *Total* non-union may occur, there being no kind of connecting medium between the fractured ends, which are also apparently diminished in size. They are freely moveable, and the limb altogether useless and wasted. (c) Most commonly; in both fragments, the medullary canal is obliterated, the ends are rounded and pointed by absorption, and covered in by the for-

mation of a tissue resembling periosteum; they are connected together by a strong *ligamentous band* or by several narrow bands, firmly attached to the bones. This new material is very pliable, and the *incomplete joint* thus constructed is moveable proportionately to the length and laxity of

FIG. 96.

such ligamentous connexion. (Fig. 96.) The internal condition is shown in Fig. 97. (d) Lastly, and rarely, a dense *capsular ligament* may be formed, and contain a fluid like synovia; the ends of bone have become smooth and polished, possibly eburnated, or covered with points,

FIG. 97.

possibly thin plates, of cartilage, and a synovial membrane similar to that of a natural articulation. Thus then a *complete false-joint* is constructed. The fractured ends, instead of being partially consolidated, as in the first condition, are freely moveable; but they have not the *useless* mobility of total non-union, nor the irregular action allowed by a loose band or bands of ligament with intervals between them and which less entirely surround the ends of bone. They are retained *in situ* by a dense and complete capsule, and cannot be displaced unless subjected to considerable force. The limb is proportionately *useful*. Certain authorities, such as Chelius\* and Hewson, supporting the assertion originally made by Boyer, have disputed the existence of this complete condition of false-joint. Several authentic cases are, however, recorded by Norris. Key† saw an instance in the spinous process of a vertebra; Brodie‡ in a rib; Kuhnholz,§ in the femur; Home,|| Cruveilhier, and Howship,¶ in the humerus; and

Langenbeck, Houston,\* Sylvestre,† and Bécarrd.‡ have made similar observations. Those of Otto§ are further testimony. Breschet|| readily produced complete false-joint, in his experiments on *animals*, in which it seems to be the most common form of union.

*Causes, and Effects of Ununited Fracture.*—The *external* causes of non-union after Fracture, may be any circumstances which occasion motion of the fragments, beyond that degree which is compatible with the formation of callus and its ossific consolidation. Unsuitable retentive appliances will have this effect, or their unsuitable application; so also, handling the part daily or even more than occasionally, during the process of repair. Hence, the practice sometimes witnessed, of frequently readjusting the limb, is as obnoxious as that which formerly prevailed, of close imprisonment and unalterably fixed position. *Internal* causes comprise; *muscular action* separating the fragments and thereby preventing union, as in fracture of the patella, and in that of the olecranon; or the interposition of any *foreign body*, whereby union may be intercepted. A portion of muscle, tendon, or a clot of blood intervening, is thus obstructive; of which two instances, by a piece of muscle, were seen by Mr. S. Cooper. A fractured clavicle, however, has been known to unite by two pieces of bone which enclosed an ossified subclavius muscle. (Bérard.) A piece of dead bone, in another case, retarded the process of repair for eight months; when the sequestrum being removed, union ensued in three or four weeks. (Schmucker.) Other local internal causes—not acting mechanically as impediments to union—pertain to the function of *nutrition*, at the seat of fracture. They are, chiefly, any obstruction to the circulation, producing local anæmia; as by early, tight, or prolonged bandaging, or by an immovable apparatus; wet, and especially refrigerant applications; or, on the other hand, inflammation, an abscess, or ulcer; paralysis, or any occasion of pressure on the nerves distributed to the seat of fracture; and lastly, disease of the bone itself. But the latter causative condition is not unfrequently a local manifestation of some blood-disease as a constitutional cause, and affecting the *quality* of the blood supplied to the part.

The influence of *blood-diseases* in preventing or retarding the formation of callus, has already been noticed among the complications of Fracture. The diseases alluded to are, chiefly, rickets, syphilis, cancer, scrofula, scurvy, fever, erysipelas; and the conditions of blood consequent on starvation and pregnancy. But opinions are, as I have said, divided respecting the alleged mal-influence of these diseases. The same adverse character is attributed also to habitual intemperance, copious hæmorrhage, or other discharges; and, in short, whatever induces general enervation of the vascular and nervous systems with failure of nutrition. That one or more of such causes may be in operation, and co-operate, without preventing or retarding the process of osseous union and firm consolidation, is certain. A remarkable case in point, of fracture of the tibia, was under my care in the Hospital. [P. p. 773.]

The *effects* of ununited fracture are entirely local and mechanical, by impairing the action of the muscles and the use of the part. The limb

becomes wasted, powerless, and useless; and the more so as non-union is complete and permanent.

*Terminations.*—Ununited Fracture frequently proceeds to a natural cure. In case (*a*), this takes place by *ossification* of the cartilaginous callus, already formed, which then becomes an instance merely of retarded or delayed union. The line of distinction between *arrest* and *delay*, in the transformation of a cartilaginous into an ossific callus, is imperceptible, and therefore doubtful, in all cases. Experience shows, that not until after four, six, or even eight months have elapsed, is firm union by unaided Nature, eventually improbable. In case (*b*)—that of total non-union—the process of natural cure supervenes by the formation of an uniting medium, and its ossific consolidation.

But, Ununited Fracture may remain in a *stationary* condition; the process of union being arrested, in either of the cases, (*a*) or (*b*). Lastly, the Fracture may become *more moveable* by the formation of a false-joint; incompletely (*c*), or completely (*d*), as a diarthrodial false-joint.

In estimating the probability of either of the latter issues; statistical results are at least trustworthy to show the comparative infrequency of non-union, in *any* form, as the *final* issue of Fracture.

The results collated in Hamilton's elaborate work,\* afford a sufficient body of evidence on this question. Amesbury alone seems to have believed in the frequency of non-union. His experience extended to 90 cases. But, Walker, of Oxford, affirms that of not less than 1000 fractures which came under his treatment at some period of the repair, he does not recollect more than 6 or 8 instances. According to Lonsdale, not more than 5 or 6 cases of false-joint, excepting those within a capsule, have occurred out of nearly 4000 fractures treated at the Middlesex Hospital. In a table of 367 cases, collected and arranged by Mr. W. Morland from the books of the Massachusetts General Hospital, extending through a period of nineteen years, only one instance of false-joint is recorded; and as only seventy-four days had elapsed when this patient was discharged, it is doubtful whether this might not have proved to be a case of delayed union simply.† Of 946 cases of recent fracture in the Pennsylvania Hospital, between the years 1830 and 1840, no instance of false union followed the treatment pursued.‡ Sir Stephen Hanmick, Liston, and Malgaigne, bear testimony also to the infrequency of these accidents in the cases which have come under their care. Hamilton has seen a considerable number of examples of non-union, but in not one of his own cases, whether in Hospital or private practice, has the bone refused finally to unite; and his opinion is, that, in proportion to the total number of fractures which occur, such cases are very rare, perhaps not more than 1 in 500. In my own experience, I may add, 5 cases only have come under my observation or treatment; as compared with many hundreds of fractures, during a period of more than twenty years. Two were fractures of the humerus, at the junction of the middle and upper third; and two were fractures of the femur; one at about the junction of the middle and lower third, and the other at the junction of the middle and upper third. The particulars of the latter case—which occurred when I was a student, at University College Hospital—are narrated in my *Principles of Surgery*, p. 711. Lastly, a compound and comminuted

\* *Fractures and Dislocations*, 1860, Philadelphia, p. 68.

† Address on Fractures, A. L. Peirson, May 1840.

‡ Norris, *Op. cit.*

fracture of the tibia, about the middle of the shaft, was followed by the separation of portions of dead bone and incomplete or cartilaginous union.

*Treatment.—Earliest occasion for interference.*—Guided by the natural course and tendency of Ununited Fracture; not until the lapse of 4, 6, or even 8 months, is the Surgeon justified in concluding that union will not take place. During, however, the latter portion of this period, and even before the expiration of the first-named period, 4 months, he will begin to *suspect the improbability* of union ensuing; this improbability increasing according to the lapse of time, without the process of repair supervening, or adequately progressing. Consequently, the earliest occasion, or period for interference, is some months *before* the fracture assumes the condition of false-joint.

*Indications of Treatment.*—Taking the structural conditions in the order already mentioned; the indications of treatment have reference primarily to non-union, in each of the two states described.

(a) With *incomplete* union, the general indication of *local* treatment is, to encourage, or excite, the process of ossification in the cartilaginous callus, so as to complete the reparation. The fulfilment of this indication consists in the continued treatment of the case as one of fracture; namely, by the reapplication of appropriate retentive apparatus, observing to correct any error in its construction or adjustment, which allowed of undue mobility, obstructed the circulation of blood, or the supply of nervous influence. By thus ensuring rest to the part, and the other local conditions that are essential for reparative nutrition, ossification may ensue. Hence, also, any topical application, previously in use, which may have reduced the nutritive vitality of the part, must be discontinued. Inflammation, and its consequences, suggest indications of local treatment. Another general indication is; to supply, if possible, any defective quality of blood referable to any of the *Blood-diseases*, which are severally known to exercise some degree of prejudicial influence on the ossification of callus. Their pathology and treatment are considered in previous Chapters. Medicinal treatment should be supplemented by hygienic measures. The physiological relation of diet to the process of fracture-union, is not more exactly understood than its relations to other processes of reparative nutrition,—an important subject demanding much further investigation; therefore, with regard to Fracture, it can, at present only be viewed empirically. Experience shows, that a liberal proportion of animal food, with wine, beer, or spirits, according to the patient's previous habits and present condition; constitute an efficacious diet; and that exercise daily in the open air, proves specially beneficial. If the limb be encased in a starched bandage, and slung from the shoulder, the patient will be enabled to move about without interrupting the consolidation of the callus.

These precautionary and soliciting measures having failed; there is no alternative but to have recourse to some operative procedure. Various other manipulative proceedings have been proposed—*e.g.* friction, or with stimulating embrocations, and the application of galvanism; but no such measure has any known direct relation to the process of ossification; nor are their results sufficiently successful to justify the further postponement of operation.

The only question, therefore, is, the *kind* of operation, which may now be requisite. It should be remembered that a *callus* already exists, only in an unossified state. It would be unsurgical to undo what Nature

has already so far accomplished, by any procedure of a destructive character.

*Acupuncture, or subcutaneous incision*, of the cartilaginous callus, has often had the desired effect of inducing ossification. Either operation is easily performed. The one by puncturing the callus in two or three places, with the view of starting as many centres of ossification; for which purpose, Brainard's perforator,\* or the Archimedean drill, being more handy, may be used. The instrument is introduced through the skin and subjacent integuments, and, having pierced the callus at one point, is reapplied at another point, and so on, without withdrawing it from the skin. The other operation is accomplished by dividing, or at least incising, the callus, subcutaneously, with a tenotomy bistoury, or a long narrow-bladed knife. In either proceeding, care must be taken, if possible, to avoid wounding any nerve or vessel of magnitude, adjacent to the callus, and to which it may be attached; and to at once close up the puncture, or the aperture, lest the fracture become permanently compound. Obviously, however, in proportion as either operation may have *this* tendency, or *that* liability, its propriety will be questionable.

In the remarkable case of ununited fracture of the femur, already alluded to, as having occurred at University College Hospital; subcutaneous section was partly successful. In May of the following year, 1848, the late Professor Miller† reported five cases of ununited fracture thus treated successfully. The operation appears to have been a compromise between division and puncture; the callus having been freely *irritated* at several points with a small tenotomy bistoury. This practice was successfully imitated by Mr. G. F. Sandford, of Davenport, Iowa, in two cases;‡ and others might be cited.

(b) *Complete non-union* suggests the same treatment—local and general; and also the removal of any other local cause which may be open to detection and surgically accessible. Thus, an intervening piece of dead bone, or other mechanical impediment to union, may be removed. These remedial measures not succeeding; then and then only is further operative assistance indicated. And what operation? There is no connecting medium whatever, and the ends of bone have already undergone partial absorption. Consequently, the indication is, to remove the comparatively lifeless and altogether ununited ends of bone. *Excision* is preferable to *scraping* or *rasping*, which, leaving the ends in a somewhat contused state, is less favourable to healing. Both modes of operation convert the fracture into compound. Excision was first practised by White,§ of Manchester, in 1760, and it has since been attended with variable success in the hands of different Surgeons. Of 39 cases, collected by Norris, in which the ends of bone were excised or rasped; 24 were successful, 7 remained ununited, and 6 were fatal. But the unsuccessful results of this, as of other operations, may perhaps be explained, by analyzing the *cases* in which the operation is practised, and the mode of its performance.

Excision for completely ununited fracture is, in my opinion, peculiarly appropriate where the ends of bone cannot be retained in apposition; owing to an *oblique* direction of the fracture, a comparatively rare case;

\* Trans. Amer. Med. Assoc., 1854, vol. vii.

† New York Journ. Med., July, 1848, p. 134.

‡ Trans. Amer. Med. Assoc., 1850, vol. iii. p. 355.

§ Dict. de Méd. vol. xiii. p. 503.

or to *deformity* of the bone, as from rickets. A successful case of this kind, in which I excised an inch of either end of bone, has already been referred to. In fracture, from, or with, *locally diseased* bone; in compound fracture, with protrusion and *contusion* of the fragments; and in all cases of fracture *completely* and *persistently* ununited; excision is specially indicated, and may be practised successfully. *Subcutaneous* or superficial bones are peculiarly eligible for the operation. Its performance should be guided by two most important rules; the one negative—not to disturb the ends of bone from their bed, more than is necessary for excision; the other—a positive injunction—to remove as much bone as may be requisite, thin slice after thin slice, if necessary, to expose a healthy surface of bone at either end. Their apposition, or at the most, easy contact, is then the only local condition essential to union. Primary union should be solicited by closing the aperture, thus endeavouring to reduce the fracture to the simple condition.

Other operations have been proposed and practised, to excite repair. The passing a *seton* between the ends, as was first successfully applied by Dr. Physick, of Philadelphia, in 1802;\* or, when this proceeding is impracticable, passing a seton *around* each end, as was suggested by Oppenheim. But, either way, this operation does not remove the inert ends of bone, nor can the fracture possibly be reduced to a simple condition. The seton should not be allowed to remain longer than to induce inflammation, without much suppuration. This may take place in a week or ten days; or by that time, the ends of bone may be in a well of pus. Success has followed this operation, in fracture of the lower jaw, the clavicle, bones of the forearm, and the humerus; while, in the other chosen seat of ununited fracture, the femur, it has been nearly a total failure. A loop of silver wire around either fragment, has been substituted for the seton; whereby also the ends have been tied together, or the wire has been tightened from time to time, until it has cut its way out. Both these modifications of the *metallic ligature* are equally objectionable, essentially, although not equally, provocative of profuse suppuration. Metallic ligatures have proved successful in the hands of Horeau; J. K. Rodgers, Mott, and Cheeseman, of New York; N. R. Smith,† and Flaubert.‡ But, Norris saw an instance of ununited fractured patella, in which this treatment was fatal on the fourth day.

(c) *False joint—incomplete*—presents a different structural condition, yet a further consequence of ununited fracture. Any operation of a destructive character, as by the removal of the ends of bone—although partially absorbed and indisposed, therefore, to unite—is overruled by the fact, that a connecting medium, in the shape of a band or bands of *ligamentous tissue*, already exists, which may be induced to become the *matrix* of ossification. Hence, in this case, the *introduction* of a *foreign body* here and there, around the false-joint, may have this result. The operation, originally proposed by Dieffenbach, can be readily accomplished; by cutting carefully down to the seat of fracture, drilling holes in the fragments, with Brainard's perforator or the Archimedean drill, taking care that the point does not slip to either side of the bone, into perhaps a large artery or nerve; then introducing ivory pegs, four, five, six, or more, and driving them home with a mallet. The fracture, thus

\* Med. Repository of New York, 1804, vol. i.

† Malgaigne's Work, trans. by Packard, p. 255.

‡ New York Journ. Med., 1839, vol. i. p. 343.

made compound, is reconverted into simple, by at once closing the incision with sutures, and lint-dressing. It may remain simple, but generally the wound reopens, with immense swelling around the part and profuse suppuration. Thence the peril, to limb and life, of this operation. The pegs must be forthwith extracted, leaving the fracture in a worse state than before; thus rendering amputation perhaps unavoidable, and even sacrificing the life by the severe constitutional disturbance. If the wound remains tolerably quiescent, and consolidation of the fracture is found to have taken place after the lapse of a month or six weeks, the line of incision must be reopened by an incision and the pegs withdrawn, their extraction being very easily accomplished owing to partial absorption or disintegration of the portions impacted in the bone. The wound may possibly again heal by primary union; or now run the course of granulation and free suppuration tediously to recovery, and with considerable impairment of the general health, consequent on the double operation and protracted process from first to last.

Various authors bear testimony to "several" and "numerous" instances of perfectly successful results, in their practice; but I am unable to find the particulars of such cases. For my own part, I have not hitherto experienced, nor witnessed, much of a satisfactory character in the results of this operation. But my experience has been limited. In one case of false-joint of the humerus, at about the insertion of the deltoid muscle, I introduced four ivory pegs. That operation failed. I repeated it, and it caused such swelling and tension of the arm as to compel me to withdraw the pegs; but the false-joint remained nearly as moveable as before this twice-performed operation. In another case, a false joint of the femur, about the junction of the lower and middle thirds; I saw the same operation performed, but it was not repeated, and the result was not more effectual.

(d) *Complete false-joint*—the most irrecoverable structural condition—suggests the same operation as for the incomplete condition; the introduction of ivory pegs, as foreign bodies, to induce ossification in the capsular ligament already existing as a matrix. But it should be thoroughly considered, whether the uncertainty of such reparation taking place, and the peril of the operation, are not advantageously counterbalanced by a condition of structure, which although not that of united fracture, is yet a firm connexion, and with which the limb is proportionately useful. Under these circumstances, it may be *better* "to let well alone."

DISUNITED FRACTURE is a parallel condition to Ununited Fracture. Union having taken place, and with firm osseous consolidation; a Fracture may again become disunited, loose and moveable. The *causes* of disruption may be local; as mechanical violence, occasioning immediate destruction of the callus, or inflammation affecting it, and operating more slowly; or possibly some constitutional causative condition, as scurvy. The *treatment* accordingly must have reference to the nature of such causes.

---

## CHAPTER XXX.

## SPECIAL FRACTURES.

FRACTURES OF THE CRANIUM.—These Fractures are so intimately related to Injuries of the Brain, that they are more conveniently considered with those lesions—see HEAD-INJURIES.

FRACTURES OF THE SPINE—see SPINE.

## FRACTURES OF THE FACIAL BONES.

1. FRACTURE OF THE NASAL BONES.—*Structural Condition.*—Displacement of the bones may be slight; or the bridge of the nose, flattened or sunk; with more or less contusion of the integuments, extending even to the cheeks. The lachrymal bone, occasionally, participates in the injury, with rupture of the lachrymal sac, or of the nasal duct. The cribriform plate of the ethmoid bone has, it is said, been found driven up into the brain, thus occasioning serious or fatal injury to that organ.

*Signs.*—Hæmorrhage from the nose is sometimes profuse and persistent. In one case, in the Hospital, a policeman—whose nose had been broken on several occasions of conflict with ruffians—nearly bled to death. The *appearance* of the nose before the supervention of swelling, is characteristic, if there be much displacement; and then, the loose mobility of the fragments, and their crepitation in the spongy swelling, when lightly handled with the fingers—feeling sometimes like a bag of fragments—will, at once, suffice to detect the nature of the injury. Discharge of tears over the face, with emphysema of the eyelids and forehead; denote an extension of the fracture laterally to the lachrymal bone. Some symptoms of concussion of the brain may accompany the fracture; or those of compression, owing, probably to an extension of the fracture to the ethmoid plate.

*Causes.*—*Direct* violence is the only mode of fracture of the nasal bones. And such force must, usually, be considerable, to break down the articulations of these bones with the frontal and superior maxillary bones. A severe blow or fall, are the ordinary causes of this injury.

*Course and Terminations.*—Union takes place, and with tolerable readiness, in most cases. But exfoliation of portions of the bones, with a fætid discharge, may prolong the recovery for some time. In one such case, under my care, the patient having broken his nose by a fall, he subsequently received some further damage from the brim of his hat being accidentally thrust over his brow in getting out of an omnibus. The angular depression, where the formerly prominent bridge of his nose had been, and the upturned or snubbed extremity of the nose, gave him an unhappily conspicuous appearance. Shortly, a fætid discharge commenced, and continued so profusely, as to run downwards into his throat when he lay down, or from the nostrils when he sat up. This offensive condition, with a claspings, bewildering pain across the forehead, and constant sleeplessness or horrid dreams, made his life miserable. Exfoliation of portions of bone, from time to time, gave him occasional relief.

*Treatment.*—Without displacement of the bones; cold lotions, or other

applications, to subdue the inflammatory swelling, will be the only interference requisite. With displacement, the bones must be adjusted by a little manipulation externally, and within the nostrils by means of a director or other such instrument. Compresses should then be applied to retain the bones in position. *Persistent hæmorrhage* can be arrested only by plugging the nares, posteriorly and anteriorly, irrespective of any immediate consideration for the fracture. This proved effectual in the severe case of the policeman. The fracture may be adjusted in the course of a few days. *Exfoliation* of the bones and discharge, must be treated according to circumstances. Alum injections, and the administration of iodide of potassium, proved signally beneficial in the case above referred to; although the history of the gentleman—a married man, and beyond middle life—gave no evidence of any syphilitic antecedents.

2. FRACTURE OF THE MALAR BONE.—Comminuted, in most cases; displacement of the fragments is inconsiderable, although spiculæ may be driven into the temporal muscle. The mobility and crepitation of the broken portions, are scarcely rendered imperceptible by the swelling, which however is often most conspicuous.

*Direct* violence is the only cause, and the violence must be very great, as the bone, thick and solid, and supported by its surrounding articulations, offers great resistance. Hence, fracture rarely occurs, compared with that of the nasal bones, although the malar is equally exposed. A heavy blow, however, on the malar bone, produces a starred and radiated fracture, just as a thick plate of glass, in a frame, is broken by a stone.

*Treatment.*—Cold lotions may be applied in the first instance. Adjustment of the fragments will hardly be necessary, but they may be retained in position by compresses suitably placed. The pain ensures rest, any attempt to masticate or speak being intolerable. Fragments driven into the temporal muscle should be removed.

3. FRACTURE OF THE ZYGOMA may occur with, or without, fracture of the malar bone. In one case, I found the *articulation* of the zygomatic process of the temporal bone with the malar, severed, unaccompanied by any fracture.

The broken or disarticulated ends of bone must be kept in apposition *secundum artem*.

4. FRACTURE OF THE UPPER JAW.—The *nasal process* of the superior maxilla is liable to fracture with the nasal bones; and this must, perhaps, occur if the fracture extends outwards to the lachrymal bone, across the nasal process of the superior maxillary bone. The *alveolar process* also, a much thicker portion of this bone, is sometimes broken. The *malar eminence*, externally, may participate in fracture of the malar bone with which it articulates; and the *Antrum* of Highmore is, sometimes, crushed.

*Direct* violence only can occasion these severe injuries. Gunshot wound, or the handle of a crane revolving and striking the face, thus produces fracture; involving, possibly, all the bones of the face in one common smash, or disjunction, with pulpification of the integuments. The face “feels like beans in a bag.” I have seen two such facial bags; the one resulting from machinery, the other from the compression of a cart wheel passing over the face.

*Treatment.*—The contusion, which accompanies fracture of any portion of the upper jaw, always requires the application of cold lotions or

the usual means to subdue inflammatory swelling. Adjustment of the fragments must be accomplished by proper manipulation, and retained by any suitable contrivance.

5. FRACTURE OF THE LOWER JAW.—*Structural Conditions*.—This bone may be broken in any part; the *body*, and particularly *between* the symphysis and insertion of the masseter muscle, rarely at the *symphysis*, in the *rami*, or the *processes*. Commonly, fracture is limited to one side of the bone. Its direction may be transverse, or oblique; and in the latter form of fracture, the pointed end of the anterior portion is apt to pierce the mucous membrane of the mouth, or to be tilted upwards by the depressing action of the genio-hyoid muscles; thus, in either way, rendering the fracture *compound*. This condition of fracture in the lower jaw, has, I believe, been questioned; but I distinctly found it in one instance of fracture of the body on the left side, which had become compound, in the course of a few days, by the tilting effect of the depressor muscles; the nature of the injury having been overlooked and no retentive apparatus applied.

The *Signs* are; some unevenness along the base of the jaw, and irregularity of the teeth, with mobility and crepitus when the parts are handled. The patient even experiences a harsh grating sound, conveyed through the temporal bone, as well as pain, on moving the jaw. The anterior portion is drawn downwards by the genio-hyoid muscles, and particularly if the fracture be in front of, and therefore unresisted by, the masseter muscle. Fracture on either side of the symphysis allows the middle, intervening, portion of bone to be drawn more downwards. In any case there is also dribbling of the saliva; which, at first, has a bloody tinge, from laceration of the gums, especially if the fracture be compound. Fracture of the *processes* is less easily recognised. The condyloid process, when detached, will be drawn forwards by the external pterygoid muscle.

*Direct* violence is always the cause of fracture in the lower, as well as in the upper jaw; and such force must be considerable, as the bone is very thick, and readily moves from side to side.

*Treatment*.—Adjustment of the fragments can be easily accomplished, but less easily retained. A pasteboard or gutta-percha splint may be moulded to the base of the jaw; the upper jaw being used as a splint above. A four-tailed bandage, with a hole in the centre to receive the chin, is then applied; two ends tied over the top of the head, and two behind the neck, thereby fastening the jaw, both ways, in position. Fluid nourishment only is allowed, which can be sucked in between the teeth. Double fracture, and near the symphysis, with greater depression of the fragment, requires the more steady and firm support of the clamp apparatus, contrived by Lonsdale. Loose teeth may, possibly, be preserved by fastening them to the sound teeth with fine gold or silver wire. But any tooth which would prevent even apposition of the fragments, should be removed. Advantage may perhaps be taken of the opening thus made, to feed the patient through a suction-tube, during the process of reparation. Union takes place usually, in a month or five weeks.

FRACTURE OF THE HYOID BONE.—This injury occurs very rarely. In one instance I have seen a fracture at the junction of the great cornu with the body of the bone, on the left side.

The mobility, and some displacement of the fragments are sufficiently characteristic.

*Direct violence* would seem to be the only occasion of hyoid-fracture, as by the grip of an assassin; but it is said to have been produced also by muscular action. Hanging, another instance of force compressing the hyoid bone, does not, I believe, produce fracture of the hyoid bone. At least in one case, having, by permission of the Sheriffs, examined the throat of a man after execution at the Old Bailey; I found no fracture of this bone, although the rope, producing a deep, purple indentation, had passed directly over the bone.

*Treatment.*—Adjustment of the fragment is easily accomplished. Its retention in position is far more difficult, owing to the mobility of the part, and the recurrence of deglutition. It has been proposed to embrace the neck in a firm pasteboard collar, as a splint; and thus fix the bone externally. The liability of displacement in other directions, by muscular action, still remains a difficulty to be overcome.

**FRACTURE OF THE RIBS, AND COSTAL CARTILAGES.**—*Structural Conditions.*—One or more ribs, even several, may be fractured. Seven and eight ribs I have seen broken, counting from the second downwards. The first, and perhaps the second rib, are seldom fractured, they being protected by the clavicle; and the last two false ribs also escape, as being floating, or freely moveable. The mid-ribs, most exposed and fixed, are, usually, the seat of fracture. Any part of a rib is liable to be broken, by direct violence; but the convexity, or near the angle, yields mostly under the force of compression. Thus the mid-ribs, somewhere in a line from the axilla downward, present the fracture commonly met with. Displacement may be outwards, or inwards; rarely upwards or downwards, the intercostal muscles apparently restraining the broken ends in either of these directions. The pleura and lung are specially liable to injury simultaneously; rarely, the pericardium, or heart, the diaphragm, and liver.

*Compound fracture* occurs sometimes, as by gunshot wound.

The *Signs* of fracture are; crepitus, and some mobility, felt on placing the hand over the seat of injury, while the patient coughs or breathes hurriedly; and some irregularity or flattening in the course of the ribs can usually be detected, at least during such respiratory action. A catching pain occasionally disturbing the respiration, elicits these signs more palpably. Hence the breathing is soon restrained, and becomes more abdominal. Hæmoptysis, or a spitting of blood, pneumothorax, or a tympanitic accumulation of air in the pleura, and general emphysema of the subcutaneous cellular texture, may be further signs of fracture; indicating that the injury implicates the pleura and lung, that both are penetrated by the fractured end, or ends, of bone. These additional *thoracic* symptoms are all-important, as the respiration will then be yet more embarrassed. But great oppression may also arise from compression of the chest by the act of fracture, without any penetration of the pleura and lung.

*Causes.*—*Direct violence* as the cause of fracture, produces displacement inwards, with, probably, some wound of the pulmonary organs, or other viscera occasionally. *Indirect violence*, as compression of the chest by a wheel passing over it, produces displacement of the fractured ends, outwards, and confusion of the viscera. The former condition of injury will, probably, be limited; the latter more extensive; the one also may be fracture of any rib, at any part of its extent; the other is generally that of the mid-ribs, at their convexity. Loss of elasticity in the ribs would seem to render persons of advanced years, more liable to fracture occurring from any

compressing force. *Muscular action* has been known to cause fracture of the ribs; as by contraction of the abdominal muscles during parturition.

*Course and Terminations.*—Fracture unattended with any damage to the thoracic organs, proceeds favourably; union of the ribs taking place, with facility, in four or five weeks. Penetration of the pleura and lung may be followed by some inflammation of either, by pleurisy or pneumonia. Usually, however, any hæmoptysis, pneumothorax, or general emphysema, ceases after a time; and any inflammatory action supervening, has not a fatal issue. Contusion of the viscera by compression may soon prove fatal; but the almost momentary subjection of the chest to such force, is sometimes followed by no unfavourable consequences, although there be extensive fracture of the ribs.

*Treatment.*—Fracture, by itself, requires only the application of a broad rib-bandage round the chest, in order to arrest thoracic respiration; thus securing the ends of bone in apposition, and at rest as much as possible. Any displacement may be overcome by compresses suitably applied; as over the sternum, to increase the convexity of the ribs, in the case of displacement inwards; or two compresses, one on either fractured end, in the case of projection outwards. The rib-bandage is itself secured in position, if necessary, by a vertical bandage over the shoulders, and abdominal strips passing round the buttocks below. These accessory restraints are useful in fat persons. A broad roll of adhesive plaster may be drawn once or twice round the chest, instead of a rib-bandage. It answers better, probably, mechanically, and is not likely to shift its position; but it is a dirty, irritating thing, and as such I rarely use plaster, unless several ribs are broken. Medicinally, an anodyne cough mixture may be of service, to allay the pain, and cough of irritation, consequent on the respiratory movements; but if the chest be well fixed, the ease experienced will be considerable.

*Penetration of the pleura and lung* is more important than the fracture. Hæmoptysis, pneumothorax, and emphysema, alike require moderate depletory measures; thus to reduce the general circulation, and to relieve the embarrassment of the respiration occasioned by compression of the lung, in pneumothorax, or of the chest, in emphysema. Venesection, therefore, sometimes proves singularly beneficial, affording instant relief. In a case under my care in the Hospital, emphysema extended from the chest downwards to the iliac fossa, on the left side; attended with the usual crepitation, stuffed appearance, and great oppression of the respiration. Mr. Jeaffreson, the House Surgeon, seeing the urgency in this case, at once bled the patient, taking away more than a pint of blood. The effect was marked, and almost magical. Panting and prostrate as the man lay, before losing blood; he soon sat up and breathed freely; recovering without any further unfavourable symptoms. Scarification of the emphysematous cellular texture may sometimes be resorted to, alone, or with venesection. But the air gradually disappears, spontaneously in most cases. *Paracentesis*, or tapping the chest, has been performed for the relief of severe pneumothorax.

*Inflammation of the pleura or lung, supervening*, must be met by the treatment appropriate for pleurisy and pneumonia.

*Compound fracture of the ribs, resulting from gunshot wound*, is similar in all respects; otherwise than relates to the treatment of GUNSHOT WOUNDS.

FRACTURE OF THE COSTAL CARTILAGES may occur in any part of

their extent from the ribs to the sternum, or at their articulations with either of these bones—a dislocation, more strictly speaking. The pathology being analogous to that of fractured ribs, the treatment requires no special notice.

**FRACTURE OF THE STERNUM.**—*Structural Conditions.*—Analogous to fracture of the ribs, in most particulars; fracture of the sternum is transverse, and usually single; but this bone may be broken into three or more pieces. Displacement seldom occurs, and then the lower portion overrides the upper. Extravasation of blood into the anterior mediastinum, injury of the pericardium and heart, or of the pleura and lung; may severally accompany fracture. Fracture of the sternum is usually accompanied with fracture of the ribs, in their convexity; the same compressing force producing both injuries simultaneously. I have never yet seen the sternum broken alone.

*Compound* fracture occurs sometimes, as by gunshot wound.

The *Signs* of fracture are; crepitus, and some mobility, felt on applying the hand over the sternum during coughing or the hurried respiratory movements; and some inequality of the bone, with any displacement, will be perceptible. The respiration is principally abdominal. Hæmoptysis and emphysema, or severe palpitation, are present, when the injury involves the lung or heart. Or these organs may evince symptoms of having suffered compression, without penetration.

The *Causes* are; *direct* violence, as the wheel of a carriage passing over the chest, or gunshot wound; but the elastic and yielding nature of the ribs and their cartilages, and the spongy texture of the sternum, resist fracture of this bone. Hence although much exposed, it is rarely fractured. *Muscular action* also is said to have caused fracture; as violent contraction of the abdominal muscles during parturition, efforts at lifting heavy weights, or a fall on the back across a beam.

*Treatment.*—Position is of some importance, to relax the abdominal muscles more especially; and thus prevent displacement of the lower portion of bone forwards, which would result in angular deformity. If the patient be recumbent, the pelvis should be slightly raised; or sitting up, the shoulders should incline forwards. A broad bandage encasing, and fixing the chest, is applied, as for fractured ribs.

**FRACTURE OF THE CLAVICLE.**—*Structural Conditions.*—The Clavicle

may be broken in any part of its extent; commonly, in one of its two curves, and particularly, in its outer or scapular concavity. Rarely, fracture occurs external to the coraco-clavicular ligament—in that part of the bone between it and the acromion. This distinction is important with regard to symptoms, causes, and treatment. Hence, fractures of the sternum are divided into those on the *sternal* and those on the *scapular* side of the *coraco-clavicular* ligament, which is attached to the rough oblique line on the under surface of about the outer inch and a half of the bone. On the

FIG. 98.

*sternal* side of this ligament, fracture is usually oblique (Fig. 98); but

it may be comminuted, from direct violence. On the scapular side also, the bone may be similarly fractured. Displacement, in any notable degree, occurs only with fracture on the sternal side of the ligament, in the outer curve where the bone usually yields. The outer or scapular portion is alone displaced; the inner portion being retained in position by the costo-clavicular ligament, and the opposed action of the sternomastoid and great pectoral muscles. The displaced portion is drawn downwards, forwards, and inwards; under, perhaps, the inner portion. This displacement is partly due to the weight of the arm, having lost its support from the sternum; but principally it results from the action of the deltoid and great pectoral muscles, the latter muscle drawing this portion of the bone forwards and inwards. The structures adjacent to the clavicle are rarely injured with, or by, the fracture. The axillary plexus of nerves and the subclavian vein, have, severally, been wounded. Both these additional injuries were present, I believe, in the fatal case of the late Sir Robert Peel, whose left clavicle was fractured, and comminuted, by a fall from his horse. The injured vein led to the formation of a "diffused false venous aneurism," as large as the hand might cover, below the fractured clavicle, and which pulsated to the touch synchronously with the action of the heart, or rather with the contractions of the auricle.

*Compound* fracture has been known to occur, by direct violence, or as the result of a very oblique fracture protruding through the skin.

The *Signs* of fractured clavicle are characteristic. On the *sternal* side of the coraco-clavicular ligament; a depression, corresponding to the displacement, is readily detected on passing the finger along the bone, crepitation also, and mobility of the outer portion, on raising and rotating the shoulder, the elbow being kept to the side. Pain is caused by this manipulation; and the patient is unable to raise his hand to his head, the support of the clavicle, necessary for this semicircular motion of the arm, having given way. The patient, with his other hand, holds the arm up to his chest, to relieve the powerless weight, and inclines his head to the injured side, to relax the muscles passing from the clavicle to the head. This peculiar attitude of the patient is accompanied with a marked falling of the shoulder inwards towards the sternum, approximating the interval between these points, thus declaring the nature of the injury almost at a glance. Examination, as above directed, will be conclusive.

On the *scapular* or outer side of the coraco-clavicular ligament, fracture is less obvious, but still easily discovered. Slight displacement of the fragment downwards and drooping of the shoulder, may be observable; but this irregularity disappears on pressing the arm upwards; and crepitus, with some mobility of the fragment, are felt on raising and depressing the humerus, the hand being placed over the shoulder at the seat of fracture. The motions of the arm are scarcely impaired, as a sufficient support in the larger portion of the clavicle remains.

*Causes.*—*Indirect* violence, the more common cause, produces fracture in the usual situation—the outer curvature, and obliquely across the clavicle. The long and slender form of this bone, and its function, that of supporting the upper extremity from the trunk, render it peculiarly liable to fracture, in receiving every impulse through any of the component bones of this extremity. Thus, falls on the hand, elbow, and shoulder especially, are common causes of fracture in the curve of the

clavicle. *Direct* violence produces fracture in the part struck, and probably of a comminuted character. Thus, any part of the bone, on either the sternal or scapular side of the coraco-clavicular ligament, may be the seat of fracture from direct violence. The subcutaneous and exposed position of the clavicle, renders it liable to fracture in this way. A heavy, crushing blow illustrates the corresponding class of causes.

*Treatment.*—On the *sternal* side of the coraco-clavicular ligament; displacement of the outer fragment, inwards, forwards, and downwards, must be overcome by giving the humerus an opposite direction, outwards, backwards, and upwards. The first direction is accomplished by

FIG. 99.

of the neck. Inclining the arm inwards across the chest, until the hand points upwards to the opposite shoulder; a few turns of a roller round the chest enclosing the arm, above the elbow, will secure this position (Fig. 99). The forearm

FIG. 100.

a *pad* in the axilla; and the latter two, by inclining the arm inwards *across* the chest and *raising* the elbow. To secure the pad and arm in this position, many contrivances have been used. Before applying any such retentive bandaging or apparatus, it is well to provide against the supervention of swelling in the arm and hand, by padding the palm with cotton wadding or other soft material, and bandaging from the fingers upwards to near the axilla. Then a good-sized pad, enclosed in a handkerchief, should be placed well up in the axilla, and the arm close to the side, so as to draw outwards the scapular portion of the clavicle to an even apposition with the sternal portion; the pad being secured in its place by tying the handkerchief at the opposite side

should then be slung in another handkerchief, from the hand to the elbow; care being taken that the elbow is well supported, upwards. Any particular shifting or loosening of these simple retentive appliances, subsequently, must be corrected; but the fracture should not be re-adjusted unnecessarily. Union will have taken place, generally, in about three weeks.

Other contrivances may, occasionally, be more suitable; and particularly in fracture of both clavicles.

The shoulder can be *drawn* backwards, and thus kept in posi-

tion, by a *figure-of-8 bandage* across the back and front of the chest, winding under either axilla. (Fig. 100.) The other appliances are the same as those already noticed; an axillary pad, and a sling for the arm. Excoriation of both axillæ is apt to be produced by this form of bandage.

*Brasdor's apparatus* removes this objection to a *figure-of-8 bandage*. Two well-padded straps are used, one under either axilla, which are buckled to a back-piece of stout leather, from which two perpendicular straps pass down to a belt around the waist; thus securing the whole apparatus in position. The back-piece consists of two portions, laced together according to the size of the chest.

Fracture on the *scapular* side of the coraco-clavicular ligament, may be treated in the same way as on the sternal side; the axillary pad, however, being of *smaller* size, the arm bandaged to the *side*, and the forearm supported in a sling, *slightly* raising the elbow.

In *children*, the clavicle may be bent, and this condition mistaken for fracture; the signs of fracture, in childhood, are also less perceptible, and obscured in a few days by soft-union. *Treatment* is often very unmanageable, by bandaging; and the fracture may, perhaps, be best secured by the starched apparatus.

**FRACTURE OF THE SCAPULA.—Structural Conditions.**—Fracture of the Scapula is liable to occur in any part of the bone; but in some parts commonly, in others rarely. This distinction has reference, apparently, to the more or less exposed situation of the bone, in its different parts. Thus, the *inferior angle* is more commonly fractured than the *body*; the *acromion* commonly; the *coracoid process*, and the *neck*, both rarely. The *glenoid cavity* may be starred, but *very* rarely.

(1) The *Inferior Angle* is simply broken off, and displaced forward, being drawn in that direction by the attached portion of the serratus magnus, and by the teres major and latissimus dorsi muscles.

The *Signs*, therefore, are; this displacement, and the mobility of the fragment apart from the body of the bone, or the stationary position of the *angle* when the scapula is moved.

(2) The *Body* may be fractured transversely or longitudinally; in the

FIG. 101.

FIG. 102.

former direction usually, and close below the spine of the scapula. (Fig. 101.) Little displacement can take place, the fragments being embraced

by muscles; but with completely transverse fracture, the lower portion is drawn forward.

The *Signs* are; some displacement, in transverse fracture discovered more readily, as an irregularity of the posterior border of the scapula; perhaps crepitus and mobility of the fragments, on using some degree of pressure to and fro in the direction of fracture.

(3) The *Acromion* may be knocked off at its tip, or nearer its root; (Fig. 102); it is drawn downwards and slightly forwards by the deltoid muscle, and the weight of the arm.

The *Signs* are very conspicuous. Downward displacement of the fragment and dropping of the arm, give a marked flattening to the shoulder; and the inequality of the spine of the scapula can be felt on passing the finger upwards in its course to the depressed fractured portion near the clavicular articulation. Crepitus and mobility of this portion of the bone are also felt on pressing upwards and rotating the arm, the other hand being placed over the shoulder; and the deformity of the shoulder then disappears, but it returns when the arm is again allowed to drop. The patient feels as if the shoulder were dropping off, and experiences a great sense of weight and powerlessness in attempting to raise the arm.

(4) The *Coracoid Process* is sometimes knocked off; it will be drawn downwards by the biceps and coraco-brachialis muscles, and inwards also by the pectoralis minor. (Fig. 103.)

The *Signs* are partly obscure; no particular alteration in the shape of the shoulder, though the apex of the coracoid process can be felt lower

FIG. 103.

FIG. 104.

than on the sound side; but mobility of the fragment, with possibly crepitus, are very perceptible on fixing the scapula and moving the arm backwards and forwards.

(5) The *Neck* of the scapula—beyond the root of the coracoid process—is occasionally broken off (Fig. 104), carrying with it the glenoid cavity, and coracoid process, and, perhaps, the acromion, with adjoining portion of the spine of the scapula (Fig. 105), which together fall downwards and inwards by the weight of the extremity.

The *Signs* are; marked flattening, and dropping, of the shoulder, a

depression under the acromion, and a tumour in the axilla; thus far simulating dislocation downwards into the axilla. But, mobility, and crepitus of this apparent head of the humerus, can be readily discovered by placing the hand on the shoulder with the forefinger resting on the coracoid process, and rotating the arm; the crepitus being transmitted through that process, which still remains uninjured in its connexion with the glenoid cavity. Moreover, the deformity of the shoulder disappears, and returns, as this neck-portion of the scapula is replaced and displaced, by pressing the arm upwards, and then allowing it again to drop.

(6) The *glenoid cavity* may be the seat of a starred or comminuted fracture, of which there is an excellent specimen in the Museum at Netley (Fig. 106). The *diagnostic signs* of such fracture would be obscure.

FIG. 105.

FIG. 106.

*Cause.*—*Direct violence* is the only cause of fracture, in any part of the scapula. The body is especially protected by a cushion of muscle, on the back and front of this portion of the bone; and the coracoid process and neck of the bone, are cushioned by the deltoid muscle. Thus protected, the violence must be very considerable, to produce fracture; not unfrequently, the subjacent ribs are broken simultaneously, and severe contusion or laceration of the soft parts, with such additional injury, give rise to serious consequences.

More than one fracture of the scapula may have occurred; or fracture, concurrently, of the upper end of the humerus.

The occasions of direct violence are various. A heavy fall on the shoulder may fracture the acromion, coracoid process, or neck of the scapula; a severe blow, as by the pole of a carriage, has fractured the coracoid process; and gunshot injury of the back may fracture the body of the scapula.

*Treatment.*—The direction of the *displacement* indicates the proper position of the limb, and the application of retentive bandaging.

Displacement forwards of the *inferior angle*, or a portion of the *body* of the bone, will be corrected by drawing the arm inwards, and thence the scapula forward, in order thus to meet the fractured portion which cannot easily be kept back. The arm must then be secured in that position,

by a few turns of a roller round the chest, and the forearm rested in a sling.

Displacement downwards and forwards, of the *acromion*, or downwards and inwards of the *coracoid process* of the *neck* of the scapula; may be rectified by elevation of the arm with an inclination inwards, in order to replace the fractured portion upwards and backwards, or upwards and outwards. In fracture of either of these portions of the bone, the downward tendency—with flattening and dropping of the shoulder—is more marked than any tendency forward, or inward. Having, therefore, secured the arm slightly in front of the chest, by a few turns of a roller; the forearm must be well supported in a sling, especially at the elbow. In fracture of the neck, an axillary pad will be necessary to guard against the recurrence of displacement. Thus, the treatment of fractures of the scapula, and of the neck in particular, resembles that for fracture of the clavicle.

*Contusion* of the soft parts, often severe, may render it impossible or improper to finally adjust the fracture, until the swelling and pain, thence arising, have partly subsided under the application of cold lotions or other appropriate measures.

**FRACTURES OF THE HUMERUS.**—Fracture of the Humerus is liable to occur in any portion of this bone; in the Upper Articular end, the Shaft, or in the Lower Articular end.

**FRACTURE OF THE UPPER ARTICULAR END** may occur in three situations. (1) *Intracapsular* fracture—within the capsule—or of the *anatomical neck* (Fig. 107) The head remains in the glenoid cavity, while the shaft

Fig. 107.\*

of the bone is drawn upwards and forwards to the front and outer side of the coracoid process. It was formerly a question whether this fracture ever occurred. The possibility has long since been verified by dissection. Such a case is described in Sir A. Cooper's work; and similar individual specimens are re-

corded as having been seen by Bichat, Delpech, Robert Smith, in two cases, Pirrie, and other authors.

**Signs.**—A projection, corresponding in situation to the end of the lower portion—the shaft, can be felt on the outer side of the coracoid process; and some flattening *lower* down, may be perceptible—the deltoid being spread inwards by the shaft. But immediately below the acromion there is no hollow, the head of the bone remaining in the glenoid cavity; and this negative difference in the outline of the shoulder distinguishes fracture of the neck of the humerus from dislocation. Crepitus, and immobility of the head of the bone, may also be felt on extending and rotating the humerus; if the muscular development of the deltoid and the swelling consequent on contusion, do not together form a cushion of such

\* This Fig. shows intracapsular fracture, with dislocation forwards, under the pectoral muscle. (Sir A. Cooper.)

thickness as to obscure these signs. Slight shortening of the arm will be discovered by measuring, as compared with the other arm, the distance between the acromion and olecranon processes. Considerable pain is experienced on moving the arm in examination; and it hangs powerless by the side.

*Impacted fracture* of the anatomical neck, is attended with a notable absence, or less degree, of the ordinary symptoms; the shaft having been driven into the head of the bone. It more resembles dislocation of the shoulder into the axilla.

(2) *Extracapsular fracture*—beyond the capsule—and of the *surgical neck* (Fig. 108), includes the portion of bone below the tuberosities and above the insertions of the three muscles into the bicipital groove, the pectoralis major, latissimus dorsi, and teres major muscles. Fracture in this situation is, sometimes, very oblique. The shaft of the humerus, below the fracture, is drawn inwards and upwards by the action of these three muscles; and the upper fragment outwards, by other three muscles, inserted into the great tuberosity, the supra-spinatus, infra-spinatus, and teres minor, counteracted, however, by the sub-scapularis muscle inserted into the small tuberosity.

*Signs.*—Deformity of the shoulder is presented—under cover of the deltoid muscle, but *lower* down than in fracture of the anatomical neck. And, the deformity corresponding to the displacement of the two ends of bone, it consists of a *double* projection, inwards of the lower end, and outwards of the upper end. Mobility of the lower end, and crepitus on extension and rotation with some inclination of the humerus inwards, and shortening of the arm, are more perceptible signs. Pain, severe during any manipulative examination, owing to irritation of the axillary plexus by the shaft-fragment, and inability to use the arm; conclude the diagnosis.

*Impacted fracture* of the surgical neck, is chiefly characterized by the absence, or minor degree, of the ordinary symptoms. But the fracture is too low down to be well mistaken for dislocation into the axilla.

(3) *Fracture of the Great Tuberosity*, is an occasional form of fracture of the upper end of the humerus. A double displacement here, also, is produced. The tuberosity is drawn outwards and upwards by the action of the three attached rotator muscles—supra-spinatus, infra-spinatus, and teres minor—this portion of the bone being under and outside the acromion. The head of the humerus is rotated inwards by the sub-scapularis muscle acting on the small tuberosity; it lies on the inner edge of the glenoid cavity, and under the coracoid process.

*Signs.*—Deformity of the shoulder, corresponding to these displacements, is always conspicuous. Marked flattening and great breadth of the shoulder even to double its natural breadth, catch the eye at once. A double projection may be felt; an outer, the tuberosity, an inner, the head of the bone; both, however, lying nearly on the same plane *horizontally*, and with an intervening sulcus or hollow below the acromion. Thus distinguished from fracture of the surgical neck, by the position

FIG. 108.

of the fragments; fracture of the great tuberosity somewhat resembles dislocation of the shoulder, by its sub-acromial depression; and, indeed, partial dislocation *forwards* might be said to have taken place. But the presence of *two* osseous projections is distinctive as to the nature of the injury. Crepitus on approximating the two portions of bone, and mobility, complete the diagnosis.

*Causes.*—*Direct* violence is, mostly, the cause of fracture of the upper end of the humerus. Thus a heavy fall on the shoulder may occasion fracture of the anatomical, or surgical neck, or of the great tuberosity. Protected, however, by the cushion of the deltoid muscle; these fractures are not common, and the first and last are rare. Age seems to favour the occurrence of fracture in the two first named parts; the anatomical neck being broken more frequently in youth, or the surgical neck giving way at the epiphysis. Union may not take place in the former situation, or ligamentous only, if the anatomical neck be completely detached within the capsule.

FIG. 109.

*Treatment.*—These three forms of fracture of the upper end of the humerus, may be treated alike, and with successful results. The fragments having been adjusted by extension of the arm; a pad should be placed in the axilla so as to prevent any re-displacement inwards; a shoulder splint of gutta-percha or paste-board is moulded to the shoulder and arm, both of which are then secured to the chest by a bandage; and the forearm rested in a sling, without raising the elbow, its weight tending favourably to prevent the recurrence of displacement upward (Fig. 109).

*Compound Fracture of the Upper End of the Humerus.*—Often comminuted, and with great contusion of the soft parts; this condition of injury occurs only from gun-shot wound of the shoulder, involving probably the adjoining glenoid cavity, or the processes of the scapula, or the axillary vessels and plexus of nerves.

*Treatment.*—Excision may be performed; when the injury is restricted to the head of the humerus, with, perhaps, splintering of the glenoid cavity or scapular processes. And the best results have followed this operation in such cases. Amputation must be resorted to in any additional injuries to the vessels and nerves.

**FRACTURE OF THE SHAFT OF THE HUMERUS.**—(1) *Below the insertion of the three muscles into the bicipital groove, and above the insertion of the Deltoid.*—Fracture in this portion of the shaft differs only from that of the surgical neck, in the relative displacement of the two portions of bone. (See Fig. 89.) The *upper* portion is drawn inwards, by the three muscles inserted into the bicipital groove; the *lower* portion, outwards and upwards by the deltoid muscle, and in the latter direction especially if the fracture be oblique.

The *Signs* also, thence arising, differ accordingly. Thus, deformity of the arm, corresponding to these displacements, is presented, and consisting

of two projections—an upper and a lower—but the upper will be felt on the *inner* side, the lower, on the *outer* side, of the arm. Mobility of the fragments is very perceptible, giving a hinge-like motion to the arm on the gentlest handling, and crepitus can be readily elicited by extension and rotation; inclination of the humerus *outwards*, with some shortening, of the arm, are equally conspicuous; and although the pain of manipulation may be less, the powerlessness is not less complete, than in fracture of the surgical neck. In a case, recently under my care, of fracture of the shaft just above the deltoid; all these signs and symptoms were well pronounced.

(2) *Below the insertion of the Deltoid.*—Fracture in this portion of the shaft differs only from that above the deltoid, in the relative displacement of the two portions of bone, which are here reversed. The *lower* portion is drawn inwards and upwards, by the flexor muscles; and the more so in proportion to the obliquity of the fracture from above diagonally across the bone. The *upper* fragment may be slightly everted. A projection, corresponding to the lower end, is most perceptible on the inner aspect of the arm; with an inward inclination of the humerus. The other signs and symptoms, mobility, crepitus, shortening, pain, and powerlessness, are similar to those of fracture above the insertion of the deltoid.

*Causes.*—Violence, directly or indirectly applied, is, generally the cause of fracture in both these portions of the shaft. Powerful muscular action has, however, been known to occasion fracture.

*Treatment.*—The ends of bone having been adjusted by gentle extension; three or four splints should be applied, so as to nearly surround the arm, and then be secured in position by a bandage. Bandaging the hand and forearm, will, as usual, be a proper precaution against œdema; and a sling is used to suspend the forearm, not to elevate the elbow, which, hanging down, tends to prevent the recurrence of displacement.

FRACTURE OF THE LOWER ARTICULAR END OF THE HUMERUS.—(1) *Transverse Fracture of the Lower End.*—In this fracture, considerable displacement of the lower or articular fragment backwards, carrying with it the forearm, is produced by the action of the triceps muscle; and a corresponding displacement forwards of the lower end of the shaft of the humerus. (Fig. 110.)

FIG. 110.

The deformity, therefore, consists of a projection posteriorly and anteriorly, which resembles dislocation of both bones of the forearm backwards; but the mobility and crepitus, on extending the forearm, and return of the displacement on relaxation, distinguish these two forms of injury; *fracture* of the humerus transversely, near the elbow-joint, and *dislocation* of both bones of the forearm backwards. Their diagnosis is obviously most important.

Fracture in this situation happens more frequently in adults, though still only occasionally.

(2) *Separation of the Lower Epiphysis.*—The same displacement

FIG. 111.

occurs, and attended with the same signs; the diagnosis from that of dislocation of the forearm backwards, is also similar.

This injury happens only in children, and not uncommonly.

(3) *Fracture of either Condyle.*—

The external or the internal condyle of the humerus may be fractured obliquely outwards, or inwards, and extending into the elbow-joint, thus completely separating the condyle. (Figs. 111 and 112.) Or again; a vertical fracture may extend from the joint upwards, bounded by a transverse fracture through the bone, thus separating *both* condyles.

With *single* fracture, there is not much displacement; but on taking hold of the process between the thumb and finger, it can be moved backwards and forwards, with crepitation; the forearm is flexed and, perhaps, supine.

With *double* fracture, there is more displacement, and especially

when the condyles are separated by pressure in the longitudinal fracture; the condyles are freely moveable, with distinct crepitation; the forearm is flexed, and, generally, in a state of pronation.

Contusion, with considerable pain and swelling, usually accompanies these fractures in the vicinity of the elbow; and particularly fracture of either, or both, condyles.

*Causes.*—*Direct* violence, as by a heavy blow or fall on the elbow,

FIG. 113.

is usually, the occasion of fracture, and of the condyles in particular.

*Treatment.*—The swelling which speedily ensues in these fractures, must be subdued, by placing the arm at rest on a pillow, and applying cold lotions, or irrigation. A bottle containing ice-cold water or lotion, with a skein of cotton in the fluid, and hanging out of the neck, forms a simple and effective contrivance. Sus-

FIG. 112.

pended over the elbow, a constant dropping irrigation can thus be maintained.

Any displacement having been corrected, the bones are best kept in position by angular splints, which well support the lower end of the humerus, and the upper part of the fore-arm, itself supported in a sling; and thus the patient is allowed to move about. (Fig. 113.) At the end of a month or so, passive motion of the elbow-joint, may be advisable, as a precaution against any tendency to ankylosis.

FRACTURES OF THE FOREARM.—1. FRACTURES OF THE ULNA.—(1) *The Olecranon*.—Transverse fracture not unfrequently occurs, with displacement upwards by the action of the triceps muscle, and which varies in extent according to the complete or partial rupture of the tendinous expansion of this muscle. (Fig. 114.) An interval between the fragments is thus presented; and the forearm being partly flexed by the unopposed action of the flexor muscles, that interval is increased. Mobility of the olecranon, and some crepitation, easily produced when the arm is extended, will confirm the diagnosis. Considerable fluid swelling over the seat of injury, may, however, soon render these signs somewhat obscure.

FIG. 114.

*Causes*.—*Direct violence*, as a smart blow with a stick, or a fall on the

FIG. 115.

FIG. 116.

elbow, is the usual occasion of this fracture; and of the contusion which then accompanies it. Powerful muscular action of the triceps will, sometimes, snap off the olecranon.

Union by ligament occurs in most cases; the length of this band varying from a line to an inch or more. (Fig. 115.) Bony union may take place when the olecranon is in perfect apposition; but not invariably, even in such cases.

*Treatment*.—Reduction of the displacement is effected by a completely extended position of the forearm; and maintained

by means of a splint applied in front of the elbow-joint, passing some distance along the arm and forearm. (Fig. 116.) This position of complete extension has been employed by a large majority of English and American Surgeons, ever since Sir Astley Cooper urged its almost obvious advantages. A slightly flexed position was advocated by Boyer and Desault, and is still preferred by most French Surgeons; chiefly on the ground that this attitude of the arm will be most convenient in the event of ankylosis. But, the rarity of permanent ankylosis after simple fracture, properly treated, whether by the flexed or straight position, overrules this consideration; and the loss of power almost inevitably consequent on the length of ligamentous union in flexure of the joint, is a result of more serious consideration.

Fig. 117.

(2) *Fracture of the Coronoid Process.*—Only 9 cases are on record—according to Hamilton—in which the symptoms were, apparently, referable to fracture of the coronoid process of the ulna; and not one of these cases was established by dissection, actually demonstrating the existence of fracture, opportunity not having permitted of this conclusive evidence. Only 4 specimens—according to the same authority—are known, illustrative, apparently, of this injury; and these are of doubtful character. The line of fracture is represented in the annexed figure. (Fig. 117.) Fracture of the coronoid process, has, generally, been supposed to occur, and co-exist, with dislocation of the ulna, or of both bones of the forearm, backwards; yet there is only *one* example, in which it is probable that this fracture occurred in connexion with such dislocation of the ulna and radius.

*Signs.*—The signs of an injury, the pathology of which is thus obscure, must necessarily be little known with certainty. As associated with dislocation, the signs of that form of injury will be present; and, probably, more prominently than those of fracture. Re-dislocation is apt to take place, when extension of the forearm is discontinued; and this sign has been regarded as diagnostic. It may be so, perhaps, in fracture of the coronoid process with dislocation of the ulna *alone*. Pertaining to fracture—there will be some displacement of the coronoid process upwards by the action of the brachialis anticus—if the fracture be situated at the *base* of the process, or beyond the insertion of this muscle. Fracture of the tip of the process, would not be attended with displacement. Mobility of the process, and crepitation, in the bend of the elbow; will confirm the diagnosis. But—observes Hamilton—“Notwithstanding the confidence with which writers have spoken of the signs of this accident, we are here very much in doubt; nor do we see how these doubts can be removed until we have in detail the symptoms of at least one example, the indubitable existence of which has been subsequently verified by dissection.”

*Causes.*—*External violence* is probably the only cause of this fracture. Direct violence, as crushing injuries of the elbow, will, of course, break the coronoid process, or any other part of the elbow-joint exposed to such force; but indirect force, as a fall on the palm of the hand, may possibly fracture the process in conjunction with dislocation backwards. *Muscular*

*action*—that of the brachialis anticus—is commonly regarded as being sometimes the occasion of fracture; but the accuracy of this received opinion is doubtful; Hamilton even alleging that there is no evidence of the coronoid process having ever been broken by muscular action.

Union by ligament seems to be the mode of reparation; and in the case dissected by Sir A. Cooper, the band was so long and flexible as to allow the fragment to move upwards and downwards in the motions of flexion and extension. Bony union may occur; but, perhaps, only in fracture at the base of the process, and if, fortunately, it be unaccompanied with much displacement.

*Treatment.*—Flexure of the forearm to a right angle, is the most favourable position for union. This position may be retained by means of an angular splint, and the forearm carried in a sling, for about ten days; care being taken to prevent ankylosis by timely removal of the splint, and use of the sling alone for two or three weeks more. It has been recommended to continue the splint for a longer period; Sir A. Cooper keeping the limb immovable for three weeks, and Velpeau extending this period to four weeks.

*Compound, and Comminuted Fractures of the Elbow-joint.*—The bones which enter into the formation of this joint are liable to fracture, severally, or in conjunction. The olecranon—exposed to external violence—is more often broken; and perhaps the articular end, or the epiphysis of the humerus; or one or both condyles. Commminution of the bones occurs often extensively, and with contusion rather than laceration of the integuments. The injured joint feels like a bag of bones, crepitating under manipulation, or movements of the joint, which is singularly loose and moveable. One or two trifling wounds, at the back of the elbow, or near the condyles, communicate with this disorganized state of the joint; which results from *direct* violence. More extensive laceration of the soft parts accompanies the fracture, when occasioned by gunshot wound.

*Treatment.*—Preservation of the limb, excision, and amputation, either of which operations may be performed primarily or secondarily; have severally to be considered, as indications of treatment.

*Compound* fracture, alone, without comminution, or much laceration of the soft parts; will allow the opportunity at least, of preservation of the limb.

*Comminution* to even a considerable extent, without much injury to the soft parts; permits excision of the disorganized joint; or this operative procedure may become necessary in the event of profuse suppuration or sloughing, after either of these conditions of fracture.

*Extensive contusion or laceration* of the soft parts, in conjunction with comminution of the bones, demands amputation; or this operation may, in its turn, be unavoidable after failure of excision.

It must be confessed, at least with regard to my own experience, that the results of treatment in these conditions of injury to the elbow-joint, are seldom successful as compared with similar treatment for *disease* affecting this joint. With compound fracture, I have seldom succeeded in preserving the limb; and the failure of any attempt has been owing in this—as in similar injuries of the joints and limbs by direct violence—to the extensive subcutaneous destruction of texture, concealed probably by an almost apparently uninjured state of the integument. Pathological anatomy as shown by dissection—has corrected the shortcomings of clinical observation.

2. FRACTURE OF THE SHAFTS OF THE RADIUS AND ULNA.—Commonly occurring in the middle of the forearm or below, and rarely, above; fractures of the forearm may be of either bone alone—ulna (Fig. 118), or radius (Fig. 119), or of both bones. Usually broken transversely or

Fig. 118.

Fig. 119.

Fig. 120.

obliquely, and occasionally comminuted; displacement generally occurs, anteriorly—owing to the greater power of the flexor muscles; sometimes, however, posteriorly, laterally or angularly. (Fig. 120.)

The usual *Signs* of Fracture are present. Deformity at the seat of fracture, corresponding to the displacement; mobility, crepitus, shortening, with some alteration in the direction of the axis of the bones, or forearm below the fracture; pain, and inability to use the hand, with some loss of pronation and supination, if the radius be fractured.

*Causes.*—*Indirect* violence is, mostly, the occasion of fracture; as by a fall on the hand. Hence the radius yields more frequently than the ulna. *Direct* violence may sometimes be the cause; the middle or lower portion of the shaft being more liable to fracture than the upper portion, which is protected by a considerable thickness of muscle.

*Treatment.*—The fractured ends having been adjusted, a pad should be laid along the interosseous space, to prevent any inclination of the bones inwards; for union or ossific deposit across this space would render pronation and supination imperfect or impossible. For this reason also, the forearm should not first be bandaged *under* the splints. A long splint, extending from the bend of the elbow to the fingers, is placed on the inner aspect of the forearm and supporting the hand. A corresponding splint on the outer side, need reach only to the wrist. Both the splints should be a little broader than the arm, so that in bandaging the bones may not be compressed; a bandage is then applied from the fingers upward; and the forearm rested in a sling.

*Compound Fracture of the Forearm.*—Usually arising from *direct* violence, there may be far more extensive disorganization subcutaneously, than appears from the comparatively uninjured integument. The question of amputation will be guided, mainly, by this consideration. Otherwise, operative interference should be postponed pending the natural tendency of the injury either to recovery, or to suppurative destruction or gangrene of the limb. This latter issue is far less frequent than in similar injury of the leg; and *secondary* amputation can then be had recourse to.

3. FRACTURE OF THE LOWER END OF THE RADIUS.—Known as Colles' fracture, when situated just above the articular surface; this fracture is generally transverse; sometimes comminuted, or impacted. Displacement of both fragments occurs. (Fig. 121.) The lower or articular fragment is displaced backwards and upwards, and slightly outwards, with some degree of similar rotation on its horizontal axis; this fragment being drawn in these directions by the action of the two radial extensors of the wrist, the three extensors of the thumb, and by the supinator longus muscle; or similar displacement with impaction may occur owing to the direction of the force of fracture, when caused by a fall on the palm of the hand. The upper fragment is pronated by the pronator quadratus and teres muscles.

FIG. 121.

The *Signs* of Colles' fracture resemble those of fracture in general, but having certain peculiar characteristics in this situation. A prominence to be seen and felt at the back of the wrist, just above the joint, corresponds to the *lower* or articular fragment; immediately above which, a depression corresponds to the somewhat depressed upper end of the fracture. (Fig. 122.) The palmar

FIG. 122.

aspect of the forearm, just above the wrist, presents the opposite appearances; a marked hollow underneath the articular fragment; and immediately above, the prominence of the *upper* fragment-end, pronated by the pronator muscles, and bulging the tendons of the flexor muscles. These appearances are, of course, more marked on, or restricted to, the

radial side of the forearm; and they are most conspicuous when the forearm is viewed laterally. The hand is prone; and drawn downwards and, pronely, inwards; presenting a concavity on the radial side of the wrist, and a convexity on the ulnar side, the styloid process of the ulna projecting under the integument. Mobility of the radius above the fracture, the lower fragment not moving with it, and crepitus, both of which are elicited on rotating the bone; pain, and dropping powerlessness of the hand, with loss of pronation and supination; supply additional signs and symptoms, which further manifest the nature of the injury.

*Comminution* of the lower or articular fragment, will render some of these signs more perceptible; mobility and crepitus, in particular.

*Impaction* of the upper into the lower fragment, would render the two latter signs imperceptible, more or less entirely, according to the firmness of the impaction.

Fracture of the lower end of the ulna, with that of the radius, simulates dislocation of the wrist backwards. Mobility of the carpal fragments in connexion with any movements of the hand, and crepitus, are diagnostic of this double fracture in the vicinity of the wrist-joint.

*Causes.*—*Indirect* violence, by a fall on the *palm* of the hand, is the usual mode of fracture, thereby breaking the radius transversely within an inch above its articular surface, perhaps also comminuting this fragment; or allowing the upper fragment-end to be driven into, and impacted in it. A fall on the *back* of the hand may cause a similar fracture, but throw the lower fragment forwards instead of backwards. Such a displacement is described by Robert Smith as having occurred in one case, and Hamilton has seen another case; neither, however, were verified, as to their pathological condition, by dissection; nor is there—observes the latter authority—to be found one such specimen in any of the pathological collections in Dublin. Colles' fracture may also, it is said, be occasioned by *direct* violence. I am not acquainted with any such case.

*Treatment.*—Reduction of the displacement often requires considerable extension and counter-extension to effect it satisfactorily, not to say completely. Two splints are commonly used; a long, curved or pistol-shaped splint, extending from the elbow to the fingers, whereby the hand can be well drawn downwards to the *ulnar* side; and a short, straight splint, extending from the elbow only to the wrist. These splints may be applied; the one along the palmar surface of the forearm and hand, and the other to the dorsal surface of the forearm; or in the opposite arrangement.

Of these two plans, I prefer the former. Thus, the pistol-shaped splint, applied from the bend of the elbow along the forearm, need only extend to the fingers; and bending them over a pad at the end of the splint, gives a flexed position to the hand which is easy and comfortable. A pad corresponding to the line of the radius, betwixt the splint and forearm, will further prevent any tendency to pronation of the upper fragment; while the curved shape of the lower end of the splint, inclining the hand to the ulnar side, corrects the displacement of the lower fragment. The short, straight splint applied to the dorsal surface of the forearm, from the elbow to the wrist, affords a counter-support; and with a pad between it and the lower fragment, *directly* prevents the displacement of this portion of the bone. The splints are bandaged from

below; the hand to the curved portion of the long palmar splint, and the roller being continued upwards around both splints to the elbow. The forearm is then rested in a sling.

The opposite arrangement is Nélaton's plan of applying these splints. The pistol-shaped splint, placed on the *dorsal* surface of the forearm, extends from the elbow along the fingers; and the open hand is thus inclined by the curved portion of the splint to the ulnar side, correcting the displacement of the lower fragment. The straight, short splint, placed on the palmar surface of the forearm, extending to the wrist or only to the end of the upper fragment, and padded along its radial border, specially tends to prevent pronation of the upper fragment. A bandage is then applied as already described; and the forearm rested in a sling.

Union ensues in about a month, but rarely without some displacement; thickening and stiffness also remaining for a considerable period. Passive motion and friction should be resorted to, in anticipation of this result.

FRACTURE OF THE CARPAL, METACARPAL, BONES, AND FINGERS.—*Simple and Compound* Fractures may occur; and with the usual signs of these Injuries. Direct violence, is, probably their only cause.

The *treatment* will consist, in the adjustment of the fragments, and their retention in position upon a gutta-percha or pasteboard splint, contrived according to the fracture.

Compound fracture may require excision or amputation. But the removal of only the injured portion of the hand, should ever guide and regulate any operative interference; the hand being a most valuable member in each of its several parts, and readily recovering from most injuries.

FRACTURES OF THE PELVIS.—1. FRACTURE OF THE INNOMINATE BONES.—*Structural Conditions*.—Commonly, the *rami* of the pubis and ischium are the seat of fracture; extending also, perhaps, from above the acetabulum backwards across the ilium towards the sacro-iliac articulation; or it may involve the *acetabulum*, fissuring its floor, or fracturing its margin. Sometimes, the acetabulum is comminuted, or simply divided into its three original segments, and the head of the femur driven into the pelvic cavity; or a portion of the *margin* being detached, dislocation backwards takes place. In one case, I found the pubic portion of the acetabulum nearly detached, and another fracture at the junction of the descending ramus of the pubis with the ramus of the ischium; thus nearly isolating the pubic bone. The preparation is in the Museum of the Hospital. Occasionally, some other and, perhaps, any portion, of these bones may be broken; as, for example, a rim-like piece of the *crest* of the ilium. Both innominate bones are not unfrequently fractured, and somewhat symmetrically; as, corresponding portions of the *rami* of the pubis and ischium.

Separation of the *symphysis* pubis, or of either *sacro-iliac articulation*, rarely occurs. I have, however, met with this injury to each of these *three* articulations in the same person; but only once.

Little, or no displacement is liable to occur, otherwise than by muscular action; the bones being well held together, and cushioned by soft parts. (Fig. 123.) But the pelvic viscera are frequently injured; rupture of the bladder or urethra, giving rise to extravasation of urine; laceration of the rectum sometimes occurring; or of the larger blood-vessels with intra-pelvic hæmorrhage. These visceral or internal injuries, are of far more serious import than the fracture in itself. Fractures of the pelvis

thus have an *analogous* resemblance to those of the ribs and sternum, and of the cranium or vertebral column, in regard to their visceral relations.

FIG. 123.

The *Signs* of fracture of the innominate bones are not peculiar. No irregularity of the bone at the seat of fracture may be discovered; but mobility and crepitus, on moving each half of the pelvis backwards and forwards, will be readily perceptible; pain also and inability to support the trunk are experienced by the patient on attempting to move or stand up. Inability to empty the bladder, or bloody urine, denotes some injury to this organ; and occurring with the accident, confirms the diagnosis. Caution, therefore, should always be observed in handling the pelvis, lest any visceral injury be aggravated. Fracture of, or involving, the *acetabulum*, is indicated by the crepitus elicited on rotating the femur, with the other hand placed over the trochanter. Detachment of a portion of the *margin*, with dislocation, is characterized by the recurrence of dislocation after its reduction, the head of the femur easily slipping out of the acetabular cavity.

Separation of the *symphysis*, or of the *sacro-iliac articulations*, allows of free mobility, and an interval may even be felt in the situation of such separation. In the case to which I have alluded, I could plainly pass my finger between the symphysis, and so far as to recognise the flat surface of the body of either pubis covered with its intermediate plate of fibro-cartilage. The transverse or connecting fibres had given way, as well as the ligaments on each aspect of the symphysis, including the strong *sub-pubic* ligament.

*Causes.*—*Direct* violence is almost the only cause of fracture of the pelvis. A heavy fall, or a crushing compression of the innominate bones, as by a cart-wheel passing over the pelvis, or the force of a squeeze between the buffers of two railway carriages; such, and similar accidents, are the ordinary occasions of these injuries; or they result from the equally formidable contusion of gunshot wounds. *Indirect* violence sometimes produces fracture of the pelvis; as of the acetabulum, when a person falls from a height and alights on his feet. Force applied from

the back may have the same effect; an instance of which is cited by Hamilton—a man æt. twenty-seven, on whose back a number of bricks had fallen while his right knee rested on the bank of a trench. Death ensued in a few days; and a fracture was found extending through the bottom of the right acetabulum, and about one inch and a half of the rim at its upper and posterior margin was completely detached, otherwise than as being retained by a portion of the capsular ligament. Dislocation upwards and backwards could be readily reproduced to and fro. The femur was not broken. Falls on the hip, striking the great trochanter, are perhaps the most common occasion of fractured acetabulum; the force then being transmitted more directly.

*Course and Terminations.*—Union of the fracture takes place generally without difficulty, resulting only in some degree of lameness. This result occurs more frequently in fracture of the acetabulum, with dislocation owing to the nature of the injury not having been detected, or the impossibility of maintaining reduction. Permanent lameness ensues. But any visceral injuries are of more serious or fatal consequence. The chief difference in such cases depends on the situation of the injury; whether, or not, laceration of the bladder opens into the peritoneal cavity, with extravasation of urine internally or externally. In the one case, death is almost inevitable; in the other, urinary infiltration behind or in front of the deep perineal fascia, will be followed by suppuration and sloughing, perilous to life.

*Treatment.*—Any visceral injury demands immediate attention. A catheter should be introduced to discover the state of the bladder. If bloody urine, or other symptoms of injury to this organ or the urethra be present, the catheter must be kept in the bladder, to prevent extravasation of urine. In the event of extravasation occurring externally, early and free incisions into the scrotum may avert the full extent of the local mischief, and the consequent typhoid disorder. But the treatment of such Extravasation of Urine is described in a subsequent chapter. The fracture itself requires comparatively little surgical manipulation. The pelvis should be bound round with a broad roller, or rib-bandage, and the patient laid recumbent at rest on a flat bed or mattress, sufficiently firm to counteract any tendency to displacement. Fracture of the acetabulum must be further secured by means of a long splint, or a hip-splint of gutta-percha, moulded to the side of the pelvis and thigh, to fix the joint.

2. FRACTURE OF THE SACRUM.—Exceedingly rare, fracture of the sacrum may, however, occur in conjunction with that of the innominate bones. The fracture then takes place at any part of the sacrum, and in any direction; but it may happen independently, and then generally below the sacro-iliac articulation, and transversely across the bone. In this condition, displacement is almost invariably the same; the coccygeal extremity being carried forwards, without probably interfering with the rectum or anus. A slight lateral deviation is sometimes produced.

The *Signs* are; an angular projection backwards at the line of fracture, and corresponding to the displacement forwards, mobility and some crepitus; with pain, greatly aggravated in any attempt to bend or elevate the body, and especially acute in any efforts at defecation.

*Causes.*—Fracture of the Sacrum arises from the same causes as that of the innominate bones; and from blows or falls on the sacrum itself, in fracture transversely below the sacro-iliac articulation.

*Course and Termination.*—If fracture of the sacrum occur in conjunction with fracture of the innominate bones, the accompanying lesions of the pelvic viscera generally prove fatal. Fracture of the sacrum alone is generally followed by a speedy recovery, although the inward displacement cannot often be completely overcome.

*Treatment.*—The displacement may be corrected by passing a finger into the rectum and pressing back the coccygeal portion of the sacrum; but great difficulty will often be experienced in retaining it there. Various contrivances have been resorted to for this purpose, such as the introduction of a wooden cylinder, or other form of compress, within the bowel. Any such body must be removed every two or three days, and an enema administered. A roller drawn firmly around the pelvis, and the support of a flat, resisting mattress, ensures the rest requisite for union. This takes place in about a month, or a shorter period, according to the less frequent disturbance of the part by the act of defæcation. Thus, in a case under Bermond's management, the rectal plug was retained without much inconvenience nineteen days, having been only once removed during that period; and union was then firm.

FRACTURE OF THE COCCYX occurs but seldom. The structural conditions, signs, causes, and treatment, are the same as in fracture of the coccygeal portion of the sacrum. The pain and inconvenience may be very persistent, after the injury itself is repaired. The sitting posture will then be made more tolerable or comfortable, by wearing a pad on each tuberosity of the ischium. A horseshoe-shaped air-cushion will also give great relief, as I have known in cases of *coccydynia*, a painful or neuralgic affection of the coccyx.

FRACTURES OF THE FEMUR.—Like other long bones, fractures of the thigh-bone may occur, in its Upper Articular end, the Shaft, or the Lower Articular end.

FRACTURES OF THE UPPER ARTICULAR END, comprise those of the Neck, within, or outside, the Capsule, and of the Trochanter alone.

Fig. 124.

(1) INTRA-CAPSULAR FRACTURE OF THE NECK OF THE FEMUR.—*Structural conditions.*—In *direction*, intra-capsular fracture of the neck of the femur, is,

generally, somewhat oblique—from above downwards and outwards, including sometimes a portion of the head; occasionally, it is quite transverse. The *capsule* and *periosteum* are generally rent asunder incompletely, but sometimes completely. *Displacement* of the two fragments usually occurs; the lower fragment, continuous with the shaft of the bone, is drawn upwards and to the outer side of the head of the bone, and rotated so that the fractured end is directed forwards (Fig. 124). The upper or articular fragment remains in position; the head of the bone being in the acetabulum, and connected by the round ligament. Displacement of the lower fragment

will be more or less complete, according to the extent of rupture of the capsule and periosteum.

*Impacted fracture* may occur, the end of the lower fragment being driven into the upper fragment.

*Signs.*—In intra-capsular fracture of the neck of the femur, the limb is shortened, and everted; with the knee slightly flexed, the toes pointing outwards, and the heel drawn up and resting on the inner side of the leg above the ankle. (Fig. 125.) The hip is somewhat flattened, the prominence of the great trochanter being less marked, and drawn upwards to the anterior superior spine of the ilium. Thus far, the injury resembles dislocation forwards upon the pubes; excepting that the limb is then abducted, and the head of the bone can generally be felt in its new position. But, with fracture, on drawing the limb downwards to its proper length, and rotating inwards, crepitus and mobility of the lower fragment will be felt, when the hand is placed over the trochanter; and this prominence of bone moves in a less regular and smaller segment of a circle than on the opposite or sound side. Pain, severe on any attempt at motion, and total powerlessness of the limb, conclude the diagnosis. *Shortening*, in the first instance, varies, from half an inch to an inch; but it increases, perhaps, to two inches or more, as the capsular ligament yields more completely, or the fragments impacted become dislodged. *Eversion* is produced, partly by the action of the external rotator muscles inserted into the great trochanter, and partly or principally, as the natural position into which the lower limb falls when left to itself. *Inversion* sometimes occurs, but very rarely; and is owing, probably, to the action of the adductor muscles, aided by some partial rent of the capsular ligament, favouring such muscular action. Thus, if the inner side of the capsule remain entire, this, it has been supposed, would facilitate inversion; but, it seems to me that a rent of the inner side of this ligament, would be more conducive to inward rotation of the femur. Dissection in cases of inversion, is wanted to establish either opinion. The position of the lower fragment in front of the upper one, is the explanation urged by Dr. R. W. Smith. Neither eversion nor inversion of the foot may be present, according to Hamilton, in some cases; the toes pointing directly forwards.

*Impacted fracture* is denoted by an absence, or minor degree of all the signs, except shortening. Some degree of shortening of the lower limb, which cannot be extended to its original length; unaccompanied by the other signs of fracture—or dislocation—and immediately consequent on some occasion of injury; is diagnostic of fracture having occurred, with impaction of the fragments,—an impacted fracture. A well-marked case of this kind, which was under my care in the Hospital, is reported in the Medical Times and Gazette, 1866.

*Causes.*—*Indirect violence*, but of so slight a character in many cases, as scarcely to exceed a stumble; will, generally, be found the only exter-

FIG. 125.

nal cause to which intra-capsular fracture of the neck of the femur can be referred. A slight trip of the foot, slip, or mis-step in going down stairs; are the usual occasions of this fracture. But, *age* very much *predisposes* to the injury. It seldom happens in persons under fifty; and the predisposing condition consists of an alteration in the structure, and

FIG. 126.

FIG. 127.

consequent direction of the neck of the femur, thence favouring the occurrence of fracture in this portion of the bone. Its cancellous and compact texture having undergone fatty degeneration, or disintegration and *atrophy* (Fig. 126), the neck gradually yields to the weight of the body; the inferior border of the neck, originally the longest, thus becomes somewhat shortened, and the whole neck drops to nearly a *right angle* with the shaft. (Fig. 127.) This horizontal direction, in particular, renders the neck less able to sustain the shock of any force transmitted through the femur, and which throws the weight of the trunk suddenly, on this portion of the bone. It snaps instantly and easily—perhaps, almost imperceptibly. Besides the predisposition of advancing life, intra-capsular fracture of the neck of the femur is said to occur more frequently in women than in men.

FIG. 128.

Union by *ligament* ensues, as the only mode of reparation in most cases (Fig. 128); or *no* union may take place, a false ball-and-socket joint forming between the ends of the two fragments. *Bony* union, at one time

Union by *ligament* ensues, as the only mode of reparation in most cases (Fig. 128); or *no* union may take place, a false ball-and-socket joint forming between the ends of the two fragments. *Bony* union, at one time

and for many years, thought never to take place, does assuredly result in some rare cases; but only, it would seem, when the capsular ligament remains entire, or the fragments impacted, whereby a due supply of blood can be speedily established.

The use of the limb is not restored under three or four months.

*Treatment.*—No bony union taking place, as the rule, in intra-capsular fracture of the neck of the femur; it will generally be useless to adjust the fracture and apply any retentive apparatus, with a view to such union; and the more so, in proportion to the years of the patient. In elderly persons, and those to whom any long confinement would be prejudicial; their general health is of more consequence than the fracture, and which is itself irreparable in advanced life.

The limb may be placed in an easy position, until pain, and the inflammatory consequences of the injury have subsided; when a splint moulded to the hip should be applied, and the limb slung from the foot by a long band passing round the neck; the patient thus being enabled to get about on crutches. Whatever reparation, and recovery from lameness, may then take place, it proceeds under the most favourable circumstances with regard to the general health, and its influence on reparation.

In younger subjects; the fracture may be adjusted, and a long splint applied, as for the treatment of other fractures of the femur.

*Impacted fracture* should be treated in the same way; but the splint is applied only for retention, as the limb cannot be extended to its original length.

## (2) EXTRA-CAPSULAR FRACTURE OF THE NECK OF THE FEMUR.—*Structural Conditions.*—In situation, extra-

capsular fracture may occur at any part of the neck external to the capsule; but generally, at the base, corresponding very nearly with the anterior and posterior inter-trochanteric lines. *Comminution* almost invariably occurs; and, probably, by the penetration of the upper fragment into the trochanteric fragment, so as to split it into two or more pieces. The *direction* of the fracture in the outer fragments, is also remarkably uniform; the great trochanter usually being divided from near the centre of its summit, obliquely downwards and forwards towards its base, and the line of fracture terminating a little short of the small trochanter or penetrating beneath its base; one or two lines also usually traverse the great trochanter, horizontally. In more than twenty specimens — observes Hamilton — there were only two or three exceptions to these general rules.

*Impacted fracture* is produced,

FIG. 129.

when the upper fragment is driven into, and partly imbedded in, the trochanteric fragment; the compact portion of which embraces, and fixes, the neck of the femur, thus shortened and slid down nearly to a right angle (Fig. 129).

The *Signs* of extra-capsular, are the same as those of intra-capsular fracture, but *more marked*. Thus, shortening, averaging one inch and a quarter—in 42 cases—may reach to two, three, and even four inches. Eversion is very conspicuous, but inversion not uncommon as compared with intra-capsular fracture. Flattening of the hip is also well marked, unless swelling, which is often considerable, has supervened. Crepitus and mobility are equally notable; and these three hip-signs, are even more pronounced with *comminuted* fracture. Pain, always severe, and total inability to move the joint, will no less attract the notice of the Surgeon.

*Impacted* fracture renders all these signs obscure or imperceptible, except shortening, which varies from half an inch to an inch. The limb cannot be extended to its original length.

*Causes*.—*Direct* violence, as by a fall on the hip, is the usual mode of fracture; occasionally, *indirect* force, as by a fall upon the feet or knees. Age has less *predisposing* influence than with relation to intra-capsular fracture. Extra-capsular fracture is said to occur mostly between the ages of thirty and forty; but Hamilton regards the liability as proportionate to advancing life, and that age may be considered as the “grand predisposing cause.” Both sexes seem equally liable.

FIG. 130.\*

*Union by bone* takes place readily, and especially with an impacted fracture. (Fig. 130.) The callus is deposited, almost invariably, along the inter-trochanteric lines; and also, not unfrequently, along the lines of the other fractures of the trochanter. This callus is abundant and irregular, projecting as spines and tuberosities; forming a knobby and spiculated crown, which embraces the upper fragment. Osseous buttresses sometimes reach even to the bones of the pelvis. The use of the limb may be restored in six or eight weeks; but lameness still continues, and with impacted fracture, this condition is permanent.

Comparing fractures of the neck of the femur, within and without the capsule; it will be seen that they differ, in their structural conditions, in the degree of their signs, in their causes, and prognosis.

*Treatment*.—Moderate extension and rest, by means of the long straight splint, is here the most appropriate mode of treatment. A bandage or padded belt may be applied around the pelvis, underneath the splint, to retain the trochanter, often comminuted, in position. The only objection

\* Intra-capsular and extra-capsular fractures of the neck of the femur; the former not united, the latter firmly united by bone. (Langstaff.)

I have ever experienced in the use of this retentive apparatus, has been, not as to its thorough efficiency, but the pain occasioned by pressure over the trochanter, owing to the contused state of the integuments in most cases. This inconvenience, however, is temporary, and can be overcome by using an *interrupted splint*.

*Impacted fracture* should be treated in the same way; although the splint must be applied only for retention, as the limb cannot be extended to its original length.

(3) FRACTURE THROUGH THE GREAT TROCHANTER.—The *direction* of fracture through the great trochanter, is a line passing obliquely upwards and outwards from the lower portion of the neck, but instead of traversing the neck completely, it passes through the base of the great trochanter, thus separating the femur into two fragments; an upper consisting of the head, neck, and great trochanter; and a lower, the shaft of the femur (Fig. 131). This fracture occurs very rarely, and it has been verified by dissection in only two cases; the one related by Sir Astley Cooper, the other by Mr. Stanley. The signs, causes, prognosis and treatment, are the same as in extra-capsular fracture of the neck.

FIG. 131.\*

*Compound fracture of the neck of the Femur*, is a very formidable injury, resulting almost exclusively from gunshot wound.

The *Treatment* is that for compound fracture, in general; hence, according to the condition of injury, retentive appliances may be used, excision of the splintered portion, or amputation at the hip, resorted to. But, experience has shown that any attempt to preserve the limb entire will be almost hopeless; and amputation, utterly hopeless; excision, therefore, remains as the only justifiable resource, followed by retention of the limb in the best position for union.

FRACTURE OF THE SHAFT OF THE FEMUR.—*Structural Conditions*.—The *situation* of fracture is, generally, in the middle third of the shaft; its *direction*, oblique downwards and inwards, or downwards and forwards in the lower third, and varying in the upper third; transverse in children; or the bone may be not unfrequently comminuted. *Displacement* of the lower fragment occurs, upwards and inwards, somewhat behind the upper fragment, and with some rotation outwards. This displacement is produced by the adductor muscles. The upper fragment is drawn or tilted forwards by the conjoint psoas and iliacus muscles, inserted into the small trochanter; and outwards by the external rotators. (See Fig. 87.)

This state of the fragments as pertaining to the middle third of the bone, existed in a case which I examined within a few hours after the

\* The line of fracture in the figure nearly coincides with the description in the text. (Sir A. Cooper.)

accident; it having then proved fatal. The preparation is in the Museum of the Royal Free Hospital.

The *Signs* of oblique fracture in the shaft, are; deformity of the thigh, corresponding to the displacement, and occasioning a muscular fulness on the inner, and less so on the outer aspect of the thigh; mobility, and crepitus, on extending and rotating the limb; shortening, to about one inch, but increasing with muscular action, and some eversion; pain, and inability to use the limb. *Transverse* fracture, in children, is accompanied with *angular* deformity; the ends of the fragments being incompletely displaced, and hitching on each other. The other signs are the same, differing only in degree from those of oblique fracture in the adult. These signs are usually so well marked, and especially those connected with the seat of fracture, that the nature of the injury can hardly be overlooked, and may be suspected at a glance. It is thus also that fracture in the *shaft* of any bone is always more readily detected than at either articular end; and where the diagnosis of the two or three fractures there liable to occur, is even more difficult.

*Causes.*—*Direct* violence undoubtedly may be regarded as almost the only mode of fracture in any portion of the shaft; unless it has occurred immediately above the condyles or immediately below the small trochanter. Thus, the passage of a loaded vehicle across the thigh, or the fall of a piece of timber directly on it, represent the occasions of fracture. *Indirect* violence, as a fall on the feet or an indirect blow, may, indeed, fracture the shaft; but, more commonly, the bone just above the condyles, or just below the small trochanter.

*Union by bone* takes place, usually, in the course of about six weeks or two months; but rarely, if ever, without some overlapping of the fragments and proportionate shortening of the limb.

*Treatment.*—Many plans of treatment have been devised, and very many forms of retentive apparatus contrived, for the treatment of fractures of the Femur.

The *long, straight splint* will be found most effectual in *all* fractures of this bone; excepting, probably, fracture near the small trochanter above, or near the condyles below; in the former of which, the upper fragment is much tilted forwards and outwards by the conjoined psoas and iliacus and by the external rotator muscles; and in the latter, the lower fragment is much drawn backwards by the gastrocnemius. As means of *extension*, the long splint must exceed the length of the limb, by five or six inches beyond the sole of the foot; while for steady *retention*, the splint should reach from near the axilla along the side of the chest and limb, to that point. These requisites are best combined in Liston's long splint; which, with a perineal band, for counter-extension, should be thus applied. (See Fig. 92.) The split ends of a roller are tied to the upper end of the splint, through two holes, and well secured; the roller is then drawn down on the inner aspect of the splint, and overlaid by a pad the breadth and length of the splint, to the foot, the pad being kept in position by a few tapes, binding it, at intervals, to the splint. Having well adjusted the padded-splint from the axilla to the foot; the roller, running between, should be drawn round the foot, across the instep, and round the end of the splint, where it is received into deep notches, with an intervening point to catch the roller; then drawn round the foot again, and so on in a figure-of-8 fashion. The foot having been thus secured to the end of the splint, as the point of extension, the roller is continued up the

limb to below the seat of fracture in the thigh; a perineal band, consisting of a handkerchief covered with oil-silk, should now be passed from the inner side of the thigh around the buttock, drawn well up into the crutch, and the ends passed through the two holes at the top of the splint. By tightening this band, the limb can be extended from below the fracture, and its adjustment having thus been completed, the ends of the perineal band are secured at the top of the splint. The roller is continued up the thigh, and around the chest and splint nearly to the axilla; further securing both fragments in position, through the medium of the unyielding splint.

The only difficulty likely to arise in the course of treatment by the long splint, is some excoriation occasionally, from the perineal band. A little temporary relaxation of the band, powdering the surface with flour or chalk, or the maintenance of extension by a weight pendent from the lower end of the splint; will usually succeed in overcoming this difficulty. In the management of a very large number of cases of fracture of the thigh, by means of the long splint and perineal band, I have never experienced any other difficulty, nor has that ever proved insuperable; while the perfect efficiency of this plan of treatment has been attested by the most satisfactory results.

Fracture of the shaft of the femur *near the small trochanter* may sometimes be adjusted more evenly—by *relaxation of the muscles*, and the application of a splint to maintain the requisite position for that purpose. The thigh is flexed on the abdomen, and the leg upon the thigh, and the limb laid somewhat on its outer side; an *angular splint* moulded to the hip and thigh, must then be applied, and, perhaps, a short counter-splint on the inner aspect of the thigh. Both are secured by a bandage.

Fracture *near the condyles*, in the *shaft*, may be conveniently associated with that of the lower articular end.

**FRACTURE OF THE LOWER ARTICULAR END OF THE FEMUR.**—The *direction* of fracture is, generally, transverse; or either condyle may be detached; thus resembling fractures of the Lower Articular End of the Humerus. These fractures also involve, or extend into, the knee-joint. *Displacement* of the lower fragment backwards is produced by the action of the gastrocnemius muscle.

The *Signs* are, usually, clearly perceptible; some deformity corresponding to the displacement, mobility, and crepitus; pain, and loss of power in proportion to the displacement.

*Impacted* fracture in this situation is liable to occur. Erichsen states that he has had several such cases under his care. In one, the upper fragment, which was very oblique, was firmly driven into the cancellous structure of the lower one. In another case, the condyles of both thigh-bones were splintered or comminuted into a number of fragments, amongst which the shafts were impacted.

*Causes.*—*Indirect* violence, as by a fall on the feet, and thence fracture of the epiphysis—transversely from the shaft, is not uncommon in children. *Direct* violence, as by a fall on the knee, or kick of a horse, may fracture either condyle.

*Union* by bone commonly takes place; and, indeed, such was the result in the more severe cases above noticed.

*Treatment.*—A *flexed position of the knee*, supported by the *double-inclined plane* or McIntyre splint, is perhaps the most effectual plan of treatment in these fractures. Inflammatory swelling of the knee-joint—

concomitant with fracture near or into the joint—must be subdued by cold lotions or irrigation.

The *starched* bandage will be appropriate in the treatment of *any* fracture of the femur—as in all other Fractures—only when retention, without any extending force, may be sufficient. It will, therefore, be found very useful after consolidation has taken place, to thus finish off the union, without further confinement to bed. Or, it may be employed from the commencement, in children and infants; where the ordinary apparatus cannot well be applied or retained. In adults as well as children, for the treatment of fractures of the thigh; Mr. Erichsen extols the starched bandage, as being suitable, in most cases, from the commencement. He has thus treated “many fractured thighs, both in adults and children, without confinement to bed for more than three or four days, and without the slightest shortening or deformity being left.” I must confess to never having been so fortunate in a single instance. In the last case where I removed the long splint, and put up the limb in a starched bandage, earlier than usual—i.e. before consolidation of the callus; the upper fragment progressively overlapped, occasioning acute pain, and the man had to go to bed again for another month.

COMPOUND FRACTURE OF THE FEMUR—often comminuted; results, usually, from direct violence, as severe contusion or gunshot injury.

*Treatment.*—The rules of treatment for Compound Fracture in general are here applicable; whether with regard to preservation of the limb, intact, excision of splintered portions of bone, or amputation. The amount of concomitant injury to the soft parts—integument, cellular texture, muscles, vessels and nerves, as well as the fracture itself; mainly determines these questions of treatment.

For *preservation* of the limb, by reparation of the fracture; a long splint should be applied, as for simple fracture; the splint however, being “interrupted” opposite the fracture, to facilitate the application of dressings. *Excision* might possibly be the means of preserving the limb, short of the comminuted or splintered portions of bone removed. But I have not met with a case as regards compound fracture of the *femur*; though I have myself succeeded in thus preserving the leg in compound fracture of both the tibia and fibula. *Amputation* may prove successful in the middle third of the thigh, but never at the hip-joint. If therefore, the fracture be so high up as to render it doubtful whether amputation in the former situation should be performed, or an attempt made to preserve the limb; the Surgeon must use his own judgment in steering between Scylla and Charybdis. In a recent case of this kind, I was compelled to have recourse to amputation at the hip, owing to the shattered state of the limb, and the persistent dribbling hæmorrhage in spite of tourniquet compression. The patient, as usual, died in a few hours.

Compound fracture, involving the *knee-joint*, necessitates amputation.

#### FRACTURE OF THE PATELLA.—

*Structural condition.*—In fracture of the patella, the line of fracture is generally transverse, and across the middle (Fig. 132), or sometimes the upper rim only of the bone. Longitudinal fracture may occur; or comminution more frequently, the bone being starred

FIG. 132.

FIG. 133.

and broken into three tolerably equal pieces (Fig. 133). Laceration and opening of the synovial capsule has been known to accompany simple fracture, as shown by a specimen in the Museum of the Royal Free Hospital. Displacement of the upper fragment, upwards, is produced by contraction of the quadriceps extensor muscle; the lower fragment fixed by the ligamentum patellæ, remaining stationary.

The *Signs* of fracture are sufficiently obvious; a depression or interval, into which the finger readily sinks, between the two fragments, and more perceptibly when the joint is flexed; mobility of the fragments, and probably some crepitus, when the limb is extended. Pain may be inconsiderable, but marked inability to raise the limb, in addition to the above signs, can never be overlooked (Fig. 134). Fracture of just the upper *rim*, without any rupture of the aponeurotic capsule of the joint, will probably render these signs obscure. In one such case, the patella seemed to me of the usual shape and size; no interval could be detected, the small crest-piece of bone not being drawn upwards, but slipping behind the patella, itself apparently entire; and thus the fragment could not be readily moved laterally, nor brought into contact with the rest of the bone. But, there was the usual powerlessness, or nearly so, in the patient's endeavour to lift his leg.

FIG. 134.

*Causes.*—*Muscular action* is the most frequent cause, producing transverse fracture. A person falls backwards, the knee is bent, and the patella snaps—as the tendon of the quadriceps extensor might be ruptured—by the sudden strain thrown on that muscle in the effort to regain the upright posture. But the fall ensues because the patella gives way, and the bone is not broken by falling on it. Consequently, this accident happens more commonly in men, and in adult life than childhood. In like manner, after fracture of one patella, the other is more liable to be broken by muscular action; increased strain being thrown on the quadriceps muscle of the other leg, in any similar effort of self-preservation. Both patellæ have been known to snap simultaneously. *Direct violence*, as by a fall on the knee, is the occasion of longitudinal, and, more especially, of comminuted fracture. According to Hamilton, such force will generally produce transverse fracture; but muscular action invariably having this effect, the greater proportion, if not all, transverse fractures, are thus produced.

The mode of *union* in fracture of the patella would appear to be of two kinds; ligamentous, (Fig. 135), and osseous; the difference depending probably on the less or more complete contact of the fragments, during the process of union. Hence the probability as to the one or the other taking place will vary according to the direction of the line or lines of fracture, whereby the fragments are subjected to displacement by muscular action—that of the quadriceps extensor, or perhaps by an altered position of the limb. *Ligamentous* union usually takes place in trans-

verse fracture; with rare exceptions, where osseous union may occur, nearly complete contact having been maintained. Union by ligament will form even when separation of the fragments extends to an inch and a half; beyond this distance, thickened aponeurotic fascia serves as the only bond of connexion. Thus the fragments may remain severed to an extent of four or five inches. *Osseous* union, apparently, takes place more frequently in longitudinal, and in comminuted fractures of the

Fig. 135.

verse fracture, marked E. A. (594), in the Museum of the Royal College of Surgeons, Dublin. Necrosis of the patella may ensue, after transverse fracture with ligamentous union; owing apparently to deficient vascular supply to the fragment affected. The upper fragment became partially necrosed, in a case recorded by Erichsen.

*Treatment.*—Position of the limb, so as by relaxation of the quadriceps extensor muscle, to bring the fragments into close apposition, is the guiding rule of treatment. The limb should be extended, and flexed on the abdomen, until the fragments would naturally fall into apposition, and this position maintained by a sufficiently elevated inclined plane on which the limb rests. Any swelling or distension of the synovial capsule

Fig. 136.

—any synovitis, consequent on the injury, having subsided, aided by an evaporating lotion; the fragments may then even be brought into contact. When, therefore, the swelling has diminished in the course of three or four days, during which period no reparation could have commenced; the fragments may be readily, and painlessly, retained in position

by the application of a bandage immediately above and below them, encircling the limb in a slightly figure-of-8 form, and tied together at the sides (Fig. 136). Sometimes the additional security of a compress just above the upper fragment may be necessary. A short back splint from above the ham to the calf, and furnished with a hook above and below to catch the turns of bandage, will further steady the fragments. The bandage should be tightened daily as the swelling subsides. Broad strips of plaster, overlapping each other, might be used instead of the bandage, but this retentive appliance cannot be tightened without re-application and disturbance of the fragments.

Various other apparatus have been contrived, but they are all alike in principle, and none of them succeed in bringing about union better than the above described.

Malgaigne's *hooks* are a contrivance whereby the fragments can be forcibly drawn together, and retained, by steel claws thrust into them, or just above and below them. If there be no risk of penetrating the joint with this instrument, violent synovitis is not unfrequently induced. I have never used the clamp in my own practice; but in one case particularly, having been asked by a surgeon to see a fractured patella which was subjected to its grasp, I found a huge globular knee, pierced by the claws of the instrument, and surrounded by a gutter of pus. Nor is this instrument necessary, if the position of relaxation be duly observed. Malgaigne, I learn from Mr. W. Adams, has used the hooks in only 14 cases out of a large number of fractured patellæ; exceptional cases, attended with unusually wide separation of the fragments.

Comparing the two retentive appliances, it may be fairly said, that the bandage in a moderately figure-of-8 form, is at least equally efficacious, and invariably safe; whereas, the hooks are unnecessary, and not unfrequently perilous.

With the simple, efficacious and safe plan of treatment I have described, *union* will be so far secure in a month or six weeks, as to allow the patient to move about; guarded by a back splint and starched-bandage. It is not advisable to have recourse to this substitute-apparatus at an earlier period; simply because the yielding ligamentous union should not be strained by any muscular action in using the limb, or the chance of osseous union be frustrated. Even after some six weeks have elapsed, the ligamentous band continues to yield; and in the course of as many months may present an interval between the fragments of several inches. For *permanent* support, I have used with advantage another simple contrivance—a laced elastic knee-cap, having a leathern receptacle to compress the patella. In one case, a gentleman, of powerful muscular development and accustomed to a sporting life, was thus enabled to go about, without any further separation of the fragments. This apparatus should be worn until the union has become firm and unyielding.

The *union-results* of this mode of treatment—by position and bandage-retention—have been, in my own practice at least, most satisfactory. In four cases, selected as having been authenticated by notes carefully taken by Mr. John B. Foster, formerly House Surgeon at the Royal Free Hospital, the principal points of interest and importance were the following:—(1) The fracture in all four cases was transverse, and occurred in the left patella. (2) Three of the fractures were caused by muscular action, the fourth by direct violence. (3) The ages of the patients were fifty-six, forty-nine, forty, thirty-three. (4) The periods when union

was found to be firm, and the support of a back splint in starch used only as a precaution, were ten weeks, six weeks, eight weeks, six weeks. (5) The extent of separation between the fragments, originally, and at the end of these periods, was as follows:—Original separation, in all the cases, two inches, slightly more or less. Union-separation, one-fourth of an inch, contact, one-fourth of an inch, one-eighth of an inch.\*

*Compound fracture of the patella rarely occurs alone. It is almost necessarily comminuted, with great injury to the joint; and results from direct violence of severe character, as some crushing force, or gunshot wound.*

The treatment will generally be amputation, without delay.

**FRACTURES OF THE LEG.—1. FRACTURE OF THE TIBIA AND FIBULA, OR OF EITHER BONE SINGLY.**—*Structural Conditions.*—The direction of fracture in the tibia and fibula is most

FIG. 137.

FIG. 138.

commonly transverse, in the upper part of these bones, especially the tibia; or it may be comminuted, and extend into the knee-joint; in the lower part, the fracture is commonly oblique, or transverse (Fig. 137); or perhaps less frequently comminuted. These differences are dependent on the causes of fracture, above and below. *Displacement* varies with the line of fracture. Angular displacement usually occurs with transverse fracture, the ends of bone remaining, partly at least, in contact. This displacement is produced by the flexor muscles of the calf drawing the bones backwards, aided by the weight of the leg, and perhaps the tilting forwards of the ends of the upper fragments by the quadriceps extensor, inserted into the tubercle of the tibia. Longitudinal displacement, with oblique fracture, is produced by the muscles of the calf drawing the lower fragments backwards and upwards. Rotatory displacement of the lower fragments may

be occasioned by inversion or eversion of the foot.

Fracture of the tibia (Fig. 138) or fibula, *singly*, is attended with less displacement; either bone acting as a splint to the other, and especially the massive tibia in relation to the fibula.

*Signs.*—The signs with fracture of *both* bones are most marked. Deformity is presented corresponding with displacement; an angular projection forwards, will be observed, usually in transverse fracture, high up; a depression on the subcutaneous surface of the tibia, in oblique fracture, lower down. Mobility and crepitus are easily produced on handling the fragments; and the outline of the leg is seen to be altered, the axis of the bones above and below the seat of fracture, forming an angle; with some shortening also in oblique fracture. Pain, as in other

\* Summary of a Paper read before the Harveian Society, London.

fractures, is occasioned by any movement, and marked powerlessness of the limb cannot be overlooked; the leg can be moved about loosely as a flail below the fracture, and lies helpless in any position in which it is placed.

Fracture of the tibia or fibula, *singly*, is attended with the same signs, but less pronounced than in the case of both bones; the sound bone, supporting the fractured bone. Fracture of the *tibia* presents the more obvious signs. On tracing down the bone, some irregularity will be discovered, and some mobility and crepitus of the fragments may be elicited. Fracture of the *fibula* in its upper two-thirds, is obscured by the peronic muscles which overlay the bone in this portion of its extent. By following the fibula with the finger, from below upwards, the signs of fracture may be rendered perceptible.

*Causes.*—*Direct* violence seems to be the only cause of fracture of these bones in their upper part. Any crushing compression, as by a wheel passing over the leg, or a jam between the buffers of railway carriages, may thus be the occasion of fracture; both bones being broken at the same height, and transversely or comminuted. Gunshot injury acts in like manner. *Indirect* violence is, probably, the more common cause of fracture lower down. A fall or leap from a height, the person alighting on his feet, breaks the tibia obliquely; and the fibula next sustaining the shock, gives way. Fracture thus seldom occurs at the same height in both bones; either bone yields at its weakest point, the tibia about the junction of its lower third, the fibula near its upper end.

*Union* by bone usually takes place in about six weeks or two months; in fracture of the fibula, a shorter period.

*Treatment.*—The fragments having been brought into apposition by moderate extension, aided by sufficient flexion of the knee, and of the thigh on the abdomen; the leg may be laid in a McIntyre's double inclined-plane splint, or that apparatus as modified by Mr. Liston (Fig. 139.) This position of the limb overcomes displacement of the upper and lower fragments, as resulting from muscular action; but displacement of the lower fragment, owing to any dropping of the leg, is still further coun-

FIG. 139.

teracted by supporting the foot in a short sock with a tape attached to the toe, which is thus secured to a brass button over the end of the foot-piece of the splint. A roller is then applied around the foot and this portion of the splint to maintain extension, and continued around the leg and splint, upwards to the lower part of the thigh. McIntyre's double-inclined plane may be *fixed* by screwing the end to a vertical iron support, and which is attached to a flat board, itself placed under-

neath the mattress of the bed on which the patient lies (Fig. 140). A more comfortable arrangement, and equally efficacious, in relation to

FIG. 140.

the union of fracture, is to suspend and swing the splint in a framework contrived for this purpose, as in Salter's swing apparatus (Fig. 141).

FIG. 141.

Various other apparatus have been designed for the adjustment of fractures of the leg. A fracture box, consisting of three splints,—a leg-rest, and two supporting side-pieces (Fig. 142), may be used and swung as a McIntyre's splint. But I have never experienced any difficulty or unsatisfactory result, which could be fairly attributed to that splint, in the treatment of ordinary fractures of the leg. Fracture, very oblique, or comminuted, may, indeed, occasion some difficulty as to the retention of the fragments in apposition. It is here that division of the tendo-Achillis seems a justifiable procedure, with the view of correcting the displacement arising from muscular contraction. This resource certainly proved effectual in one case under my care, where the tibia was broken just above the ankle-joint, attended with marked retraction of the foot, and threatened protrusion of the upper end of the fracture. Erichsen divided the tendon, apparently with less success, in two cases.

2. FRACTURES OF THE LOWER ENDS OF THE TIBIA AND FIBULA, OR OF EITHER BONE SINGLY.—*Structural Conditions.*—Four forms of fracture are

liable to occur near the ankle-joint :—(1) fracture of the articular end of the tibia, obliquely from without downwards and inwards ; and of the fibula about three inches above the ankle ; (2) fracture of the fibula about

FIG. 142.

three inches above the ankle, with the tip of the internal malleolus of the tibia, this double fracture constituting *Pott's Fracture*, a very common

FIG. 143.

form (Fig. 143) ; (3) fracture of the fibula two to three inches above the external malleolus, with rupture of the internal lateral or deltoid ligament (Fig. 144) ; (4) fracture of the internal malleolus of the tibia.

FIG. 144.

Displacement in these Fractures varies ; in fracture of the Tibia and Fibula, the upper fragment of the Tibia usually projects *inwards*, and both fragments of the Fibula also in that direction ; in fractures of the Fibula and Tibia, or of the Fibula alone, the same displacement of its fragments occurs—*i.e.*, inwards towards the tibia ; in fracture of the internal malleolus of the Tibia, displacement of this fragment is still inwards.

Dislocation occurs, not unfrequently, in connexion with each of these Fractures, and with that in particular of the inner malleolus *alone* ; which, I believe, seldom happens without, and from, dislocation of the tibia outwards. Respecting fractures of the *fibula*—Hamilton writes : “In *all* the fractures which have been produced by falls on the bottom of the foot, and in all except

one produced by a slip of the foot, the accident was accompanied with a dislocation of the ankle; the foot being turned outwards." The exceptional case was doubtful.

*Signs.*—Deformity is presented, corresponding to the displacement of one or both fragments, with, perhaps, dislocation; and mobility with crepitus, discovered on handling the part.

Fracture of the articular end of the tibia obliquely, and of the fibula, produces a notably increased breadth of the ankle-joint, between the malleoli, with some eversion of the foot, and obliquity of its axis, the toes being turned outwards and the heel inwards.

Fracture of the lower end of the fibula, and of the internal malleolus, or Pott's fracture, is accompanied with a very notable eversion of the foot; the sole being turned somewhat upwards as well as outwards, so that the outer edge is directed upwards, and the inner side downwards, on which the patient rests. Thus, Sir A. Cooper, describing his own case, observes: "I broke my right fibula by falling on my right side, whilst my right foot was confined between two pieces of ice; and I could with difficulty support myself to a neighbouring house by bearing on the inner side of the foot."

*Causes.*—*Indirect* violence is certainly the more common cause of these Fractures; either by a fall or jump from a height, breaking the tibia, and fibula secondarily; or by violent eversion or inversion of the foot, breaking the fibula, with the internal malleolus or rupturing the deltoid ligament; or snapping off the inner malleolus alone. The relative frequency of the two latter modes of indirect force has been doubted; most surgical authorities regarding violent eversion as the more frequent; but Dupuytren found inversion to be the ordinary occasion of fracture. Thus, in 200 cases of broken fibula, 120 were produced by inversion or twisting the foot inwards, and 60 only by eversion or rolling of the foot outwards; the remaining 20 arising from *direct* violence applied to the bone itself.

*Union of fracture*—not involving the ankle-joint—takes place readily; and without any appreciable displacement, under proper management and supervision.

*Treatment.*—In all these Fractures, McIntyre's double-inclined plane splint, or Liston's modification of that apparatus, will be found a most efficient means of retaining the fragments in position; and the more so

FIG. 145.

proportionately to their mobility. The trough in which the leg rests, steadies the upper fragments; the foot-piece counteracts any tendency to twisting of the foot inwards or outwards; and the sock supports the heel.

Any marked tendency to eversion of the foot, as in Pott's fracture,

may be more effectually restrained by Dupuytren's splint; a short, straight splint applied to the inner side of the leg, from the knee to the foot. (Fig. 145) The pad should be doubled just opposite the inner malleolus, and a roller wound round the foot and splint in a figure-of-8 form; thereby drawing the foot inwards over the thick pad as a fulcrum, and the roller is then continued upwards to the knee to steady the splint.

*Compound Fractures of the Leg, and of the Ankle-joint.*—In the former situation, compound fracture of the Tibia and Fibula, or of the Tibia alone, happens more frequently than similar injury of any other bone. (Fig. 146.) It was, therefore, selected as the typical form of such Injuries in describing COMPOUND FRACTURE generally. (Chapter xxix.) Its Pathology and Treatment are there considered.

FIG. 146.

FIG. 147.

In relation to the *ankle-joint*, compound fracture (Fig. 147) presents no differences of practical importance. The same considerations guide as to the preservation of the limb, excision, and amputation.

**FRACTURES OF THE TARSAL, METATARSAL BONES, AND TOES.**—These bones are liable to both Simple and Compound Fractures, and with the usual signs of such injuries.

*Fracture of the os calcis* presents particulars worthy of notice. The bone is broken transversely, or comminuted occasionally; and the line of fracture may be either *behind* the lateral ligaments, or through the *body* of the bone. In the former situation, there will be some displacement, the posterior fragment being drawn upwards by the muscles of the calf; in the latter situation, this fragment is retained in position by the lateral ligaments and the strong interosseous ligament.

The *Signs* of this fracture vary accordingly. Marked flattening of the heel on its plantar aspect, or even a depression upwards, and projection of the fragment posteriorly, with mobility and crepitus; denote fracture

behind the lateral ligaments. Comparative absence of these signs, and particularly of the deformity of the heel, denotes fracture more anteriorly, or that across the body of the bone.

*Causes.*—*Direct* violence is, probably, the only cause of Fractures of the Bones of the Foot; excepting, very rarely, in fracture of the os calcis. This bone may be broken transversely, by the powerful action of the muscles of the calf.

*Treatment* consists, as usual, in the adjustment of the fragments, with relaxation of any opposing muscular action; and their retention in position. A gutta-percha or pasteboard splint must be contrived according to the fracture.

In fracture of the os calcis, the tendency to displacement and the more severe contusion may require the support of a McIntyre's splint.

*Compound* fracture generally allows only of excision or amputation. But—as in regard to the hand—the removal of any portion of the foot should be guided by great circumspection and judgment; having due regard to the injured part, and the preservation of this valuable member.

## CHAPTER XXXI.

### DISEASES OF BONE.

#### INFLAMMATION OF BONE.

BONE, or the *Ossæous tissue*, with its investing *Periosteum*, and the *Endosteum* or *Medullary Membrane* of long bones; are, severally, subject to Inflammation. But the pathology of Inflammation as affecting each of these structures is intimately associated, and they are commonly affected simultaneously or consequently. It will, therefore, be more natural to describe in consecutive order; first, the structural alterations pertaining to Ostitis, Periostitis, and Endostitis, and then their diagnostic characters, causes, consequences, and treatment.

(1) OSTITIS OR INFLAMMATION OF BONE.—The cellulo-fibrous network—the organic basis of the lamellæ in the compact and cancellated structure of Bone, with the vascular network ramifying in the Haversian canals and cancelli, is alone the *seat* of inflammation; the inorganic matter, superadded to the fibrous network in the process of ossification, not being subject to any perversion of nutrition or other vital change.

The blood-vessels become enlarged—as shown by Von Bibra and Barwell—giving an injected red appearance to the portion of bone undergoing inflammation; and the fibrous matrix, probably, passes into a state of fatty transformation, as in inflammation of most other textures. The inorganic or earthy matter undergoes merely a disintegrative separation from the fibrous matrix with which it was intimately connected, but retains its chemical composition; and is then absorbed. Such are the earliest structural, and chemical alterations in the inflammation of bone. A change of consistence—softening—accompanies this fatty liquefaction of the organic matrix and unloosening of the inorganic matter. But the Haversian canals, lacunæ, and canaliculi soon become the seat of disintegration and absorption, whereby these natural cavities are rendered

more conspicuous under the microscope; or, opening into neighbouring cavities, irregular spaces are formed. The compact structure thus acquires a rarefied or porous character, presenting the appearance of cancelli; while the cancellated portion is exaggerated. Within these spaces the fatty matter and earthy salts—detritus of the osseous tissue—accumulate; and the products also of inflammation are deposited. They consist of plastic lymph and exudation matter, or pus; the one kind of deposit resulting in induration and hypertrophy of the bone, the other in increased softening and disorganization.

The description of *these* changes belongs to the consequences of Ostitis.

*Serofulous* ostitis, structurally resembles simple inflammation of bone; the osseous substance undergoing disintegration and absorption. Thence the bone is light, soft, and oily. But the rarefied cancelli or spaces in the compact texture, are filled with peculiar products; a red jelly-like matter, or occasionally, a deposit of tubercle. The former is always diffused. The concomitant chemical changes—according to Dr. Black's analyses—consist in a considerable increase of fat in the diseased bone, a large diminution of the salts of lime, a diminution of the organic matrix, and an increase of the soluble salts. Associated with these destructive alterations, minute projections of bone from the walls of the cancelli, evince an attempt at osseous reproduction, thus corresponding to the induration or sclerosis which results from simple inflammation of bone.

*Tubercle* in bone may be either diffused or circumscribed; the latter form being comparatively rare. *Diffused* tubercle occurs commonly in the shaft of long bones. It occupies the cancelli, and appears as a nodulated, or granular, yellowish mass of soft consistence; extending frequently along the whole length of the shaft. *Circumscribed* tubercle is deposited most frequently on the outside of the skull, beneath the periosteum, constituting the *strumous* node; and scarcely less frequently, in the cancelli of the articular end of a long bone, usually the tibia. Tubercle in bone sometimes becomes actually *encysted*; as well as in the lungs, in which organs I have seen cretaceous tubercle enclosed in a distinct cyst.

Tubercular deposit, in either form, is prone to undergo *softening*; the diffused, it is said, passing into this state, less frequently and rapidly than the circumscribed. This change is always one of serious consequence. The softening of tubercular deposit, induces, or is attended with, inflammation of the surrounding bone, and suppuration. An *abscess* thence results, and the bone around becomes condensed and indurated. Or, Caries and Necrosis ensue, destroying the osseous texture. Thus, softened tubercle, a curdy unhealthy pus, and carious or necrosed portions of bone, are commonly found associated and intermixed. The matter extending, may sometimes find its way to the surface; and a chronic abscess, communicating with the bone, remain, discharging, or with little disposition to heal. Or, the matter may find its way to a neighbouring joint, destroying the articulation. But, the comparatively limited localization of tubercle, diminishes the perilous results of these destructive changes. If the shaft of a long bone be affected, the articular ends are, generally, free; and if either end of the bone be the seat of tuberculous deposit, the shaft escapes.

*Syphilitic ostitis* does not seem to be distinguished from simple inflammation of bone by any structural differences of practical importance.

(2) PERIOSTITIS.—Inflammation of the periosteum is usually connected with that of the bone itself—ostitis. The periosteal membrane becomes

more vascular, thickened, softened, and loosened from its connexion with the subjacent bone. These alterations may be seen, sometimes, in the bone of a stump, after amputation. Subsequently, an osseous deposit may take place between the periosteum and bone, with some enlargement and induration of that portion of bone, constituting a *node*.

A *syphilitic* node, which may be regarded as the type, arises from an effusion of lymph between the periosteum and bone; and proceeding from the former, at length involves the bone.

A *strumous* node, on the other hand, consists of scrofulous matter between the periosteum and bone, in consequence of a carious state of that portion of bone.

Suppuration will be noticed as a consequence of Periostitis.

(3) **ENDOSTITIS.**—Inflammation of the endosteum, or membrane lining the medullary canal, and cancelli, is, probably, of less frequent occurrence. This membrane, however, undergoes analogous changes to those of the periosteum, when inflamed—increased vascularity, and thickening. A deposit of lymph or pus ensues, in consequence of endostitis.

**SIGNS.**—*Ostitis*, affecting the deeper portion of the substance of a bone, is unattended with any appreciable signs, in the first instance. A deep-seated wearing pain, generally precedes any alteration of external appearance. This pain is more severe at night, and aggravated by changes of weather; thus resembling rheumatic pain, for which it may be mistaken. Enlargement of the bone at length becomes perceptible; with, perhaps, some redness, œdematous swelling, and tenderness of the integument. This swollen state of the integument renders any enlargement of the bone more apparent than real. Softening of the bone, in some portion of its substance, may eventually be detected on pressure; but the diagnosis will be sufficiently obvious, without subjecting the patient to the pain of such examination.

*Scrofulous* ostitis is attended with more considerable enlargement of the bone, and of an indolent character. The surrounding integuments are œdematous, white, and painless; becoming somewhat red and tender, as suppuration supervenes. The concomitant symptoms of scrofula will also determine the diagnosis.

*Syphilitic* ostitis must be diagnosed entirely by the concurrence of present and past symptoms of Syphilis.

*Periostitis.*—The symptoms are similar to those of ostitis, but more simultaneous, and superficial. A painful, puffy swelling, is presented; the pain subject to exacerbations, and the swelling acquiring a bony hardness. These diagnostic characters are well illustrated by an ordinary syphilitic *node* in a subcutaneous bone, as the shin.

*Endostitis* is not characterized by any peculiar symptoms, apart from those of *Ostitis*.

**CAUSES.**—Inflammation of bone usually results from *external* violence or from exposure to cold; but it arises under the influence of some predisposing *constitutional* condition of disease. These predisposing causes comprise secondary or constitutional syphilis, or the excessive influence of mercury—of rare occurrence now-a-days; the scrofulous taint; rheumatism; and probably other conditions affecting nutrition. Either class of causes—the traumatic or the constitutional—may be *alone* sufficient to induce osseous inflammation. The bones most liable to inflammation are, however, those most exposed to the action of external agents. Hence, the tibia, cranium, and especially the frontal bone, the

clavicle, sternum, ribs, and bones of the foot and hand, are most commonly affected.

CONSEQUENCES.—The consequences of inflammation of bone have been incidentally noticed in describing its structural conditions; and particularly in connexion with serofulous ostitis. They may now be more definitely stated as follow:—(1) *Absorption* and *rarefaction* of the bone having taken place; the osseous texture may be found in this state, before the supervention of much deposit. (2) *Induration* or *sclerosis*, having taken place; an increasing deposition of plastic lymph and its ossification, results in considerable thickening of the substance of the bone, and irregular osseous deposit on its free surfaces. Thus, a long bone becomes thickened in the diameter or substance of its shaft; and deposition proceeding within the medullary canal, its bore is narrowed; while periosteal deposit, at the same time, enlarges the circumference of the bone. Elongation of a long bone is, sometimes, consequent on its inflammation. The tibia has thus become longer than its fellow by nearly two inches. The osseous substance, resulting from inflammatory induration, is more solid, heavier, and harder than that of healthy bone, increasing even to the consistence of ivory; and the nutritious foramina are said to be increased in size. This state of hypertrophy corresponds to the inflammatory solidification of parenchymatous organs. But, as regards bone, it is a termination by restoration to health, or something beyond the natural condition of healthy bone. (3) *Suppuration* of Bone—another consequence of inflammation, of an opposite character to induration—merits a separate notice; also *Caries* or ulceration of bone; and *Necrosis*, which is analogous to sloughing or mortification of the soft textures.

TREATMENT.—In *traumatic* and *acute* inflammation of bone—whether in the form of Ostitis or Periostitis—the ordinary remedial measures for Inflammation will, usually, suffice. Warm fomentations, leeches, and rest, with the administration of calomel and opium, are appropriate. In *constitutional* and *chronic* inflammation, this treatment must be supplemented, or partly superseded, by the general treatment for secondary syphilitic affections, scrofula, or rheumatism. Iodide of potassium is thus often singularly efficacious, in syphilitic or rheumatic ostitis or periostitis.

Tension and insupportable pain are more readily and permanently relieved by free incisions, than by any medicinal treatment. In periosteal tension, these incisions should be made down to the bone; in tension resulting from ostitis, an incision may be prolonged, by means of a Hey's saw, through the bone, down to the medullary canal, as Mr. Erichsen recommends. Trephining the bone has been resorted to for the relief of osseous tension. Chronic thickening, unattended with much pain, may be removed or lessened by the application of blisters, iodine and mercurial ointments.

SUPPURATION OF BONE.—Suppuration, in connexion with bone, is liable to occur in either of the three situations described with reference to inflammation; and it may be either diffused or circumscribed; these conditions being also, less definitely, acute or chronic suppuration, respectively. Thus we recognise;—(1) *Osteo-myelitis*, *diffuse* suppuration of bone, within the *medullary canal* and cancelli; (2) *Diffuse Periostitis*, and *Periosteal Abscess*; and (3) circumscribed *abscess* of Bone, within either the cancellated or compact structure.

(1) *Osteo-myelitis*.—This condition certainly occurs, and not unfrequently; but—as Mr. Holmes observes—it is less frequently recognised

at the bedside than in post-mortem examinations. The results are diffuse suppuration, the cancelli being found loaded with pus, while the medullary membrane is usually injected and often sprinkled with ecchymoses; the periosteum is often partly separated from the bone, but the osseous texture has not generally undergone any appreciable change. At this stage, in the larger bones, the disease usually terminates fatally. Otherwise, the pus may penetrate into adjoining parts, probably into the nearest joint; or central necrosis may ensue.

The *Signs*—during life—are neither absolute nor obvious. Separation of the periosteum, with diffused pain in the bone, and diffuse inflammation of the integuments, are equally the symptoms of osteo-mylitis and of diffuse periostitis. An absence of effusion between the periosteum and bone is distinctive of osteo-mylitis; but this condition can scarcely be determined by external examination of the bone, and is often rendered more obscure by the superimposed œdematous swelling.

The *cause* is usually some injury implicating the medullary membrane and cancellated structure of the bone affected. Thus, osteo-mylitis, not unfrequently follows amputations, and other operations exposing the medullary canal.

It runs a rapid course, is commonly succeeded by pyæmic infection, and thence terminates fatally.

*Treatment.*—*Preventive* measures afford the only reasonable chance of anticipating this issue; the cure of pyæmia being beyond the reach of any known remedial agents. The ambiguous symptoms of diffused pain in a bone, with perhaps, some œdematous swelling, will, therefore, warrant the Surgeon in ascertaining the state of the periosteum, to determine the diagnosis. Under these circumstances, an early, free incision should be made down to the bone.

If the periosteum is discovered to be separating, without any notable effusion between it and the bone, it will be justifiable to *trepphine* the bone, with the view of giving exit to any matter which may have formed in the deeper cancellated structure. *Excision* of the affected portion of bone, or *amputation* of the limb, must be had recourse to, as more extreme measures.

(2) *Diffuse Periostitis.*—This diseased condition is of rather frequent occurrence; but it has hitherto been less noticed in surgical works than its importance demands. Diffuse Periostitis—according to Mr. Holmes' observations—appears to consist in the partial separation of the periosteum from the bone; by effusion of lymph or other products, on the surface of the latter. Copious suppuration soon spreads along the bone, detaching the periosteum, often from one end of the bone to the other. At an early period, neither the periosteum nor the surface of the bone is visibly inflamed. The latter, indeed, may look white and bloodless, or sometimes, slightly worm-eaten; it yields, on pressure, large drops of blood from the periosteal vessels passing into it, and its superficial layers are more readily separable from the deeper osseous texture, than in health. Necrosis is soon established, the whole diaphysis of the bone usually, perishing; leaving the articular ends unaffected, and therefore not involving the neighbouring joint. Sometimes, it does not escape. The long bones are more often affected than the flat or irregular bones; and, in the great majority of cases, the *femur*.

*Signs.*—Arising insidiously, an œdematous, painful swelling is presented—diffuse cellular inflammation—resembling acute rheu-

matism. But, suppuration soon following, the diagnosis is at once determined.

The *causes*, would seem to be some injury to the bone, occurring, however, in a scrofulous or weakly person. The disease is said to be met with more commonly about the age of puberty, and in boys more than in girls.

It rapidly runs its course; pyæmia frequently supervenes and proves fatal; or the matter burrowing among the muscles, forms numerous fistulous openings, exposing necrosed bone. The dead portion is detached much sooner, apparently, than in ordinary necrosis; and reparation also seems to be equally active.

*Treatment*.—Early and free incisions are here, also, primarily important. During the process of cicatrization, injections of very dilute hydrochloric acid may be used, as highly recommended by Chassaignac, to cleanse the suppurating cavity and hasten exfoliation of the dead bone. A generally stimulating plan of treatment will be required to support life through this trying ordeal.

*Chronic periosteal abscess remaining*, requires no special treatment.

(3) *Circumscribed Abscess of Bone*.—Always a chronic condition; this state of suppuration differs also from diffused suppuration, in its limited extent, and in being distinctly circumscribed. The abscess, thus defined, is seated within the substance of a bone, usually its cancellated structure; the cavity is lined by a distinct pyogenic membrane, and the surrounding bone is more vascular than natural, and much indurated. The size of this cavity is never large, probably not exceeding that of a small chestnut, and containing two or three drachms of pus, greenish-yellow or dark coloured. Always situated in one of the long bones, the abscess is commonly located in its upper or lower articular extremity, and very rarely within the medullary canal of the shaft. The *tibia* is most frequently affected, and its upper end near the knee-joint; its lower end near the inner malleolus, next in order of frequency; and among other bones, the lower end of the humerus near the elbow, and the femur, have severally been found the seat of circumscribed abscess. Sir B. Brodie first discovered and described this abscess, and pointed out its appropriate treatment; since the time of his observations, it has occasionally been met with by other surgeons; and recently, Mr. T. Carr Jackson contributed an instructive Paper with three cases bearing on the subject.

*Symptoms*.—Pain is at once the earliest, and most significant symptom. It is of a heavy, aching, and eventually, throbbing character; more severe occasionally, or perhaps periodically—generally during the night, and persistent for a considerable period—being probably of some years' duration. This pain is referred to a particular part of the bone at one extremity—in for example, the head of the tibia; and a point of greatest intensity can be discovered by careful palpation with the finger, where the slightest pressure produces excruciating agony. A small and slight puffy swelling, or induration, surrounds this spot; and the skin may be adherent to the periosteum, without presenting any discoloration. Beyond this external appearance, little or no enlargement of the bone accompanies the remarkable pain of which the patient complains; and there is an absence of any symptoms of joint-disease.

*Diagnosis*.—The nature of this disease may, however, be mistaken for chronic rheumatism, or periostitis; or still more probably, for a neuralgic or hysterical affection. The *persistence* of the pain is the most distinctive character of circumscribed abscess of bone.

*Causes.*—This abscess can, sometimes, apparently be referred to injury, or exposure to cold. The influence of tubercular disease, is very uncertain. Early adult life seems to be the period most liable; but the ages in recorded cases have varied from 13 to 50. Males and females have been affected indiscriminately.

*Course and Terminations.*—The abscess slowly enlarging, by the excavation and condensation of the surrounding bone, never attains a large size. Ultimately, it opens into the neighbouring joint, which thus becomes disorganized; and a disposition to this result is evinced by synovial distension and swelling from time to time, after exercise. Or the abscess *may* open externally, and discharge its contents with complete relief to the previous suffering. Cicatrization follows, the cavity filling up as in the termination of other abscesses; and the fibrous material which occupies the space, probably undergoing ossification, obliterates any remnant of the abscess.

*Treatment.*—No topical applications or medicinal treatment have the slightest curative efficacy. But the operative proceeding proposed by Sir B. Brodie is at once simple and safe, affords immediate relief and a permanent cure. It consists in trephining the bone over the seat of abscess, and in thus giving vent to the pus. Chloroform having been administered, a crucial incision is made immediately over the painful spot externally, and extending down to the bone. A small trephine, having no projecting rim to oppose its entry, is then applied, and worked through the indurated bone; penetrating to some depth, and entering the cavity of the abscess. The circle of bone is detached and removed by an elevator or gouge, and the pus evacuated. Or, a drop may appear, and the bone must be penetrated further by the gouge until the cavity is entered. Sometimes no pus is discovered on raising the circle of bone; the exposed surface should then be pierced in various directions to find a drop, and the oozing aperture freely enlarged with the gouge. Otherwise, an abscess may exist, but remain undiscovered. This misadventure happened to an experienced Hospital Surgeon; the limb was amputated, and an abscess found at a small distance from the seat of perforation; showing that the removal of a small portion more of the bone would have preserved the limb. The preparation is in the Museum of St. George's Hospital. Only a small quantity of matter will issue in any case, the abscess itself being small. But the cavity having been fairly opened, the relief following the cessation of tension is instantaneous. A poultice or water-dressing will suffice during the course of reparation; which proceeding uninterruptedly, a permanent cure is established.

An error of diagnosis even may be unimportant as regards the favourable result of this simple operation. For if the disease prove to be chronic osteitis—as happened in the case of one of Sir B. Brodie's patients—the removal of a piece of bone will relieve the pain, and may induce a healthier action.

*CARIES OR ULCERATION OF BONE.*—The term Caries has been applied to different morbid conditions of Bone. By some Surgeons it has been used to denote scrofulous ulceration, exclusively; and by others, to represent a morbid condition peculiar to bone, as distinguished from that of ulceration affecting the osseous texture. But the pathological identity of Caries and Ulceration is now generally acknowledged; and as such I use the term to signify Ulceration, modified only by the textural peculiarities, of Bone.

*Structural Conditions.*—Caries is essentially a disintegration of the osseous texture; and like ulceration of the soft textures, it may be presented in two forms—as enlarging a pus-discharging cavity or abscess in the *substance* of Bone, and as affecting the *surface* of a Bone.

Carius bone is softened, and easily breaks down under pressure with a gritty resistance; it is porous, and infiltrated with a reddish-brown oily fluid, and granular inorganic matter—the *débris* of the disintegrated texture. Small detached masses of dead bone may be found associated with the carious bone. It has a greyish, brown, or black colour, but the surrounding bone is highly vascular. Beyond and around the carious area, induration and hypertrophy may have taken place; the circumferential substance of the bone being dense, and presenting externally osseous nodules or spicula, with thickening of the periosteum.

In the *substance* of bone, the appearance of Caries is more marked in the cancellated structure, which is also more especially the seat of caries. The enlarged cancelli are filled with the detritus, and their walls are in a softened state; the whole crumbles down under pressure with the finger, or may be readily penetrated by a probe, and yields with a grating sensation. This condition is commonly found in the articular extremity of a long bone; as that of the *tibia* or *jémur*, in *scrofulous* disease of the knee-joint affecting either bone.

On the *surface* of a bone, Caries presents a drilled, worm-eaten appearance (Fig. 148). The periosteum is loosened or detached, thickened, vascular and villous. The projections, thus formed, pass from the under surface of the periosteum in corresponding depressions in the bone, its compact structure having acquired more the open character of the cancellous. The textural condition of the bone is similar to that already described as pertaining to deep caries. Superficial caries is, perhaps, more commonly seen in the *cranial* bones, and as resulting from secondary *syphilis*. A somewhat significant resemblance exists between the forms of syphilitic ulceration in bone and syphilitic eruption on the skin. Thus, Mr. Paget has described, *annular* or circular, *reticulated*, and *tuberculated*, ulcers of bone. But these various forms are more interesting pathologically, than diagnostic.

The *Signs* of Caries, are the characters of carious bone, as just described. They are not declared until abscess having formed and discharged, the bone becomes exposed, or accessible. Superficial caries is more open to examination; but the introduction of a probe will readily discover the state of the bone, both in it and deep caries. Both forms of Caries, deep and superficial, are attended with pain, more or less deep-seated, redness and swelling of the integument; followed by suppuration and the formation of abscesses. The soft parts around then present the usual characters of increased swelling, fluctuation, and discoloration. Any such abscess bursting, discloses the carious state of the subjacent bone, or leads to a carious cavity, as discovered by a probe. Fistulous openings remain, discharging unhealthy pus mixed with the granular detritus of bone. (Fig. 149.) Large, outcropping, abortive granulations spring up; and the surrounding integument has a congested purplish appearance. Caries evinces little disposition to undergo any reparative changes,

FIG. 148.

FIG. 149.

The *Causes* of Caries are those which produce inflammation of bone, especially as occurring under the influence of some *constitutional* condition. Scrofula and syphilis thus not uncommonly affect the bones, and in the form of Caries; the disease arising often, apparently, without any external occasion of injury as an exciting cause.

*Treatment.*—The removal of any cause in operation is the primary rule of treatment in this, as in all other conditions of disease. Hence the remedial measures appropriate for Constitutional Syphilis or Scrofula, will be requisite, in most cases of Caries. Rest of the affected part is highly advantageous; but any topical applications, as counter-irritation, by iodine, blisters, or issues, are useless, compared with constitutional treatment. In an *early stage*, the disease may thus be arrested and the bone restored to a healthy state.

Or, under the influence of this treatment, disintegration proceeds only so far as to gradually remove the affected portion by a gritty discharge; recovery then taking place by granulation.

In a *chronic* state, the disease is beyond the power of restoration, and reparation is unable to discharge the carious portion of bone piecemeal.

*Operative* interference, therefore, now becomes necessary. The diseased bone may be removed by excision, of either the affected portion only, or of the whole bone; or amputation may be unavoidable, owing to the extent of the disease, or after excision, as the last resource.

*Excision* of the carious portion. This should always be a patient proceeding, never a “brilliant” operation. The bone having been exposed by a crucial incision, the diseased portion must be removed piecemeal by means of a gouge. Various forms of this instrument are used, according to circumstances. The ordinary scoop-gouge (Fig. 150) is generally most convenient; and the rose-head osteotrite will often prove very serviceable in finishing off a carious cavity. Care should be taken in working with a cutting-gouge, lest the instrument suddenly slip, and be driven accidentally into the soft parts. A steady, slow movement of the hand, and grasp of the instrument almost to the point, are the best precautions against any such misadventure. The carious portion of bone yields to the gouge with a gritty resistance; whereas the sound bone remains firm, and vascular. The *extent* of bone to be removed may, therefore, be determined by these characters; portions of softened, crumbling bone should be scooped out, until the firm, rose-coloured bleeding bone is reached. The surface or cavity, having this healthy character, is then dressed or plugged lightly with wet lint, and the

FIG. 150.

tions of softened, crumbling bone should be scooped out, until the firm, rose-coloured bleeding bone is reached. The surface or cavity, having this healthy character, is then dressed or plugged lightly with wet lint, and the

wound allowed to fill up and heal by granulation. In this way I have removed, more or less successfully, carious bone from nearly every bone. The whole rim of the spine of the scapula having been excised in one case, the patient—a lady of very delicate health—recovered slowly but soundly. In another case, I removed the whole of the middle third of the shaft of the tibia, excepting a shell of bone posteriorly. Granulations, healthy and abundant, sprang up, and nearly filled up the large cavity; but the patient by the rules of the hospital, as to time, left incompletely cured, and I do not know the result.

The *articular end* of a bone—affected by Caries—may require excision, as will be fully explained in treating of Diseases of the Joints.

Excision of the *whole* bone is rendered necessary by an extent of disease beyond the range of either of the previous partial operations, in the shaft or articular end.

*Amputation* is justifiable only as the last resource. The foot, for example, may be removed for carious disease involving the tarsal bones; or when excision has failed.

**NECROSIS.**—The death of a portion of bone is analogous to Mortification of the soft parts; and it has the same pathological relation to Caries that Mortification has to Ulceration. Caries is molecular death or disintegration of the osseous texture; Necrosis, the death of a visible portion or mass of bone.

*Structural Condition.*—Necrosis—like Caries—may affect the *substance*, or the *surface*, of a bone. In the one form of necrosis, the dead portion is named the *sequestrum*, a term more particularly applicable when the piece of bone is loose and enclosed by new bone; and when limited to the deepest portion of bone around the medullary canal, this is sometimes named *central necrosis*; while, in the other form, a superficial scale-like portion of dead bone is designated an *exfoliation*.

Necrosed or dead bone, is rough, hard and white; becoming brown or black when exposed to the action of decomposing pus and the air, from sloughing of the integument. It is avascular, not yielding any blood when wounded, and insensible.

The *whole substance* of a bone, or its *central* portion only, may be in this state; in point of extent also, the whole length of the shaft of a long bone is sometimes necrosed, and occasionally, even the epiphyses are involved. But, the periosteum, at first adherent, soon loosens its connexion with the subjacent dead bone, and deposits ossific lymph between itself and the surface of the bone. This deposit undergoing ossification, forms a sheath of new bone over or around the dead portion, which thus becomes enclosed in an osseous sheath. The periosteum is the chief, but not the only source of osseous reproduction in necrosis. Respecting this vexed question; observation has shown that the original bone itself is an important source of new bone—by granulation—in the absence of the periosteal membrane, or in central necrosis; and that the medullary membrane may contribute its share. The articular ends, in particular, evince a remarkable ossific power, when the shaft of a long bone is removed. Apart from the osseous texture and medullary membrane; the soft tissues around the bone may also acquire the power of forming ossific deposit. The dead portion, at first continuous with the healthy bone, loses its connexion at the line of continuity; the living bone detaching itself from the dead. Ulceration takes place in the course of that line, and forms a groove around the junction of the dead portion of

bone; this groove deepening, at length completely detaches it. This twofold process goes on simultaneously, though not perhaps equally; constituting a *separation* of the living from the dead bone, and *reparation* chiefly by the periosteal reproduction of a sheath of new bone enclosing the dead portion. Both changes are slowly progressive. But at length, the *sequestrum* becomes complete and ensheathed.

*Exfoliation*, or superficial necrosis, presents the same appearances as to the state of the dead portion of bone. But, it results generally from the destruction of the periosteum; consequently, no periosteal sheath of new bone is produced. The plate of dead bone is detached—as in deep necrosis—by linear ulceration forming a groove circumferentially; but, the detached portion not being ensheathed by new bone, it is thrown off from the surface or exfoliated, and exposed by open abscesses or sloughing; or it can be easily removed surgically by forceps. The periosteum of the *cranial* bones, even when uninjured, does not seem to have the power of forming a sheath of new bone; and thence the same result ensues—exfoliation.

The *Signs* of Necrosis are, the characters of necrosed bone, as already described. But—as with Caries—these characters are not declared until abscess having formed and discharged, the bone becomes exposed or accessible. Exfoliation is more open to examination; and the introduction of a stout probe will readily discover the rough, loose sequestrum; or, when visible, it may be recognised by its dead white appearance.

Necrosis is attended with violent and deep-seated pain, considerable redness and swelling of the surrounding soft parts. Suppuration ensues sooner or later, in consequence of inflammation of the bone—ostitis, having led to and being connected with the necrosis, or as the result of prolonged irritation of the sequestrum—itself a foreign body. Pus collects around the sequestrum, and interrupting the complete formation of the periosteal sheath of new bone, leaves apertures therein, named *cloacæ*; through which, sinuous tracks between the sequestrum and fistulous openings in the integument, become established. Thus is presented the structural condition of necrosis, commonly seen. (See Fig. 149.) Unlike Caries, this condition occurs more frequently in the shafts, than in the articular ends, of long bones; and usually in the compact, rather than the cancellated, structure of any bone.

*Central* necrosis is necessarily more obscure, owing to the depth of the morbid condition. The symptoms resemble those of chronic abscess in the substance of bone. Deep-seated and, perhaps, throbbing pain, with some swelling of the bone, or puffiness over a particular spot; are the more characteristic symptoms, and their persistence is even more significant.

*Causes.*—*External* and *traumatic* causes seem to have a more absolute effect in producing necrosis, unaided by any predisposing constitutional influence, than in relation to caries. Any injury detaching the periosteum, will probably be followed by more or less necrosis; excepting in the cranial bones, or others which are highly vascular. Violent contusion may so damage the osseous texture and medullary membrane, as to produce necrosis. Severe cold, as in frost-bite, and deep burns, are also immediate causes. Powerful irritants have a marked effect, apart from any inflammatory action. Thus, the fumes of phosphorus, in lucifer-match manufactories, often produce necrosis of the lower jaw; this powerful irritant entering the bone, apparently, through carious teeth.

Any condition of inflammation of bone—ostitis, periostitis, or osteomyelitis—may also induce necrosis.

*Constitutional* causes are very influential; sometimes predisposing only, or frequently producing, necrosis. Scrofula, syphilis, and formerly, the excessive administration of mercury, represent this class of causes; but necrosis occasionally, results from typhoid fever and other exhausting diseases.

*Consequences.*—Continued suppuration accompanies necrosis, and in proportion to its extent. The matter burrows among surrounding muscles, and disorganizes the whole substance of the part; while the numerous sinuses opening externally and communicating with the bone, continue to discharge an unhealthy pus. Large, protuberant granulations, springing up around the orifices of these passages, evince an abortive tendency to close up the soft parts; but reparation of the bone, by the formation of a periosteal sheath, is far more active. The ulcerative detachment of the dead portion of bone, sometimes extends to a large vessel, or the point of the sequestrum may be driven into an artery in some movement of the limb; giving rise to serious hæmorrhage externally, or the formation of aneurism. But these perilous consequences are rare. Hæmorrhage from ulceration, occurred in a case of necrosis of the femur which thus involved the popliteal artery, as shown by Dr. Porter in the "Dublin Journal," vol. v.; and in two other cases the artery was wounded by a sequestrum during active movements of the limb: one of which is related by Dr. Byron in the "Med.-Chir. Rev.," vol. xxiv., and the other by Dr. Jacob, in his "Diss. Med.-Chir. de Aneurismo," Edin., 1814. Mr. Stanley mentions a case in which the capsule of the knee-joint was penetrated by the pointed end of the necrosed shaft of the femur. Mr. Holmes has seen fatal hæmorrhage from the lingual artery in disease of the jaw, the nature of which is not stated; and from the aorta in caries of the spine.

*Treatment.*—The removal of any cause in operation, must be the primary consideration. *Traumatic* causes, which have already expended their force, so to speak, in producing necrosis, are obviously not under control. But, as arising from detachment of the periosteum, exfoliation may sometimes be prevented by timely replacement of this vascular membrane; or if adhesion takes place between the bone and adjoining soft parts, or granulations spring up from the surface of the bone, a new periosteum will be gradually formed.

*Constitutional* causes cannot be altogether overcome, but their full effect may be prevented. Hence, the medicinal treatment appropriate for scrofula, or constitutional syphilis, proves very beneficial in most cases.

*Suppuration* and *abscess* must be treated on ordinary principles; while the accompanying hectic and constitutional irritation of dead bone, should be supported by a tonic and stimulant plan of treatment with nourishing diet.

*Extraction of the sequestrum.*—The dead portion of bone is a foreign body. Unless, therefore, it be thrown off by Nature, it must be removed by Art. Its removal is determined, both in point of time and the extent of dead bone to be removed, by the ulcerative line of demarcation and the detachment of that portion; a process of some weeks' or months' duration, and the progress of which should be ascertained, from time to time, by examination with the probe. A loosened sequestrum, imprisoned

within a sheath of new bone, can only be extricated by surgical interference. The operation consists in cutting down upon the bone, and extracting the sequestrum, by means of serrated bone-forceps. (Fig. 151.) In making the incision, advantage is taken of the course of the fistulous tracks leading to the cloacæ in the bony case; and then the latter apertures are made available for removal of the sequestrum. Sometimes, one of the cloacæ is sufficiently large to allow of the extraction of the sequestrum through it. Or the cloacæ may be enlarged, or two apertures thrown into one by excising the intervening portion of the bony case, with strong-cutting pliers, straight, or angular bladed. (Figs. 152, 153.) Or again, it may be more convenient to divide the sequestrum by the same instrument, and extract either fragment separately. The removal of any portion of the bony case, is undesirable, as the new bone is not reproduced, and the limb, therefore, remains proportionately weakened.

FIG. 151.

FIG. 152.

FIG. 153.

Hæmorrhage occurs freely during this operative procedure; the blood springing from the vascular soft parts around, or welling up from the new bone. But, it can generally be arrested by pressure.

The bottom of the wound should be lightly dressed with lint; any inflammation consequent on the operation must be subdued by ordinary treatment; and eventually the limb should be supported by a starched bandage until granulation is complete and the bony case has acquired sufficient strength, to bear the weight of the body or the movements of the part. I have thus, from time to time, removed several loose sequestra from the lower half of the shaft of a femur; guided by the sinuses, and preserving the osseous case which had formed around the bone. In a compound fracture of the tibia with detachment of the periosteum; the end of the upper fragment to an inch and a half in extent, separated as a sequestrum, which I removed, together with several small scaly and spiculous portions from the lower fragment. Union ensued, but imperfect consolidation; a slight hinge-like mobility remaining for some months. An *exfoliation* may be

thrown off naturally; but this process will be much facilitated surgically by incisions, when the dead portion has separated.

*Excision of the whole of the bone necrosed, or short of its articular end.*—This operation may, occasionally, be had recourse to in *extensive* necrosis. Thus, the lower jaw has not unfrequently been removed for necrosis caused by the fumes of phosphorus. The entire shaft of the radius, leaving its articular ends, was excised by Mr. Savory, on account of necrosis; and afterwards, the bone was reproduced from either end to such an extent, that in eight months there remained an interval of only

FIG. 154.

an inch and a half, and this appeared to be gradually diminishing. The fibula also has been excised. Removal of the ungual phalanx of a finger, for necrosis from whitlo, has proved perfectly successful in preserving the end of the finger. These results are sufficient, to encourage the practice of excision in other cases of extensive necrosis. In operations for bone-excision, in necrosis, as of the lower-jaw; a short, narrow-bladed saw will often be found very convenient. (Fig. 154.)

*Amputation* must be regarded as an extreme resource, but justifiable as a sacrifice of the limb for the preservation of life. In necrosis involving the neighbouring joints; or where the limb has become disorganized by prolonged and profuse suppuration; or the general health undermined by hectic; amputation is unavoidable. Thus, in a case of necrosis of the femur consequent on typhoid fever in India, the whole shaft of the bone was involved, the limb enormously thickened, and the muscles were matted together. I amputated the limb close to the trochanter, and the patient made an excellent recovery, regaining his general health. And in the more rare cases, also, where a main artery is opened by ulceration, or wounded by the sequestrum; amputation will generally be preferable to ligature of the vessel, *in situ*, or of the main trunk.

**RACHITIS OR RICKETS.** — *Structural condition.* — This disease affects more or less the whole osseous system. The earthy matter of the bones is diminished, and the organic basis, therefore, proportionately increased; the cancelli are enlarged and filled with a brownish-red fluid. Bones in this state have acquired great softness and flexibility, thence undergoing remarkable changes of shape, in consequence of the weight of the body, or other forces to which they are subject. The bones of the limbs in particular become curved and distorted, the pelvis collapsed and twisted, the thorax contracted above and enlarged lower down by the dragging weight of the abdominal viscera, and the spine often undergoes lateral curvature. The cranium appears enlarged, owing perhaps to the imperfect development of the facial bones; presenting a large head and diminutive face.

The *Signs* of rickets are some of these peculiar deformities of the osseous system. They occur also in connexion with manifestations of scrofula.

The *Causes* of this disease are obscure. It would appear to be a condition of imperfect formation of the osseous texture; rickets never

arising after the bones have become fully ossified and consolidated; nor, indeed, after the age of puberty. It is a disease of childhood or infancy, and possibly commencing in foetal life; although its results remain in the adult.

*Termination.*—The bones become strengthened by osseous deposit in the parts most requiring support; the long bones acquiring increased thickness in their small curvatures, and the deposition extending even into the interior, so as to partially obliterate the medullary canal.

*Treatment.*—The primary indication obviously is, to supply the deficient earthy matter; and so, probably, arrest the disease. But no known medicinal preparation seems to have this effect. The phosphates of lime, or lime-water, have been administered; but in several instances I tried them without any perceptible result. Iron and quinine combined, often prove more beneficial. These medicinal tonics, with due regulation of the bowels, nutritious diet, pure air, sea-bathing, frictions, and other means for improving the general health; constitute the most effectual plan of treatment. Daily exercise may be taken advantageously; but the bones of the lower limbs should be relieved from the weight of the body, by the patient reclining at intervals during the day, and wearing steel-supports so applied as to resist any tendency to curvature. Many a little, scrofulous child—pot-bellied and bandy-legged, may thus be reared to man's estate; when Nature will complete the cure.

**MOLLITIES OSSIIUM—OSTEOMALACIA—MALACOSTEON.**—*Structural condition.*—This diseased state of the bones is far more rare than rickets, only a few instances having been recorded; but it is also far more serious. The earthy matter is greatly diminished, but replaced by a peculiar reddish gelatinous matter, chiefly fatty, and containing nucleolated nuclear cells, which have been described by Mr. Dalrymple.

This matter occupies the cancelli, which are considerably enlarged, and cavities in the compact texture; infiltrating the whole substance of the bone, until, as Dr. Ormerod remarks, it more resembles fatty matter enclosed in a periosteum than a bone. Bones thus affected, are soft and flexible; on section, the osseous texture yields a gritty sensation, and has a reddish-brown or maroon colour, exhibiting the peculiar gelatinous matter in an extremely rarefied osseous texture. The chemical composition of bone in this state—according to Dr. Leeson's analysis—is; in 100 parts—18·75 animal matter, 29·17 phosphate and carbonate of lime, and 52·08 water.

Commencing, apparently, in the cancellous tissue, the compact portion may retain its natural consistence, as an outer shell of bone; and the whole length of a long bone may not be affected. But many bones are always simultaneously diseased. Fracture, or bending without fracture, ensues, according to the extent of the disease. When softening is limited to the *internal* part of the bones affected, leaving an outer shell of hard bone, fracture is liable to occur; in one case, related by Tyrrell, 22 fractures happened; in another, by Arnott, 31 fractures. When the disease involves the *whole thickness* of the bones, they become bent in various forms, and to an extreme degree; presenting the most remarkable and frightful deformities. For example, the thighs have been bent, until the feet touched the head.

Mollities ossium and Rickets have some structural characters in common; the marked diminution of earthy matter, and rarefaction of the osseous texture; both diseases also affect more or less the osseous

system generally. But the gelatinous matter is peculiar to mollities ossium. In respect of its fatty character, the disease has some affinity to fatty degeneration; while, in virtue of the nuclear and nucleated cells, a few of which may be caudate-shaped, there would appear to be some alliance to the structural elements of Cancer.

*Signs and Symptoms.*—Certain premonitory symptoms, usually, precede fracture or deformity from mollities ossium. Wandering pains in the affected bones are experienced, and of a rheumatic character, but more severe and persistent. Marked failure of the general health accompanies these osseous pains; while great exhaustion and some emaciation precede any perceptible change in the bones. Then a fracture here or there, and progressive deformity, leave scarcely any doubt as to the nature of the disease.

*Diagnosis.*—From *Rheumatism*, it is at once diagnosed by these manifestations of morbid osseous condition; from *Cancer*, by the very general distribution of the disease, affecting more or less the whole osseous system, and by the deformity. Thus, according to Litzmann, in 85 child-bearing women, the whole skeleton was affected in 6 cases, and all the bones except those of the head in 2; and in 46 other cases, all parts of the skeleton were diseased in 21, and all the bones except those of the head in 6. From *Rickets*, as well as other diseases, Mollities Ossium may be distinguished by another symptom. The state of the *urine* is peculiar. It contains a great abundance of earthy matter, which was shown by Mr. Solly to be phosphate of lime, removed from the bones and eliminated through the kidneys. But the urine may also contain a peculiar substance, nearly allied to albumen, and in great abundance. According to the analysis of Dr. Bence Jones, in Mr. Dalrymple's case, this substance is the hydrated deutoxide of albumen, and that 66·97 parts were passing out of the body in every 1000 parts of urine. Here, therefore, there was as much of this albuminous substance in the urine, as there is of ordinary albumen in healthy blood; an ounce of urine passed was equivalent to an ounce of blood lost, as regards its albumen. "The peculiar characteristic of this hydrated deutoxide of albumen was its solubility in boiling water, and the precipitate with nitric acid being dissolved by heat and reformed when cold. By this reaction a similar substance in small quantity may be detected in pus, and in the secretion from the vesiculæ seminales. The reddening of the urine on the addition of nitric acid might perhaps lead to the re-discovery of this substance; when found, the presence of chlorine in the urine, of which there was a suspicion in the above case, should be a special subject of investigation, as it may lead not only to the explanation of the formation of the albuminous substance, but to the comprehension of the nature of the disease which affects the bones."

*Causes.*—The pathological cause of mollities ossium is unknown. But the disease in no way arises from an imperfect formation of the osseous texture, and does not generally occur before the middle period of life, or subsequently; thus, also, differing from rickets. It would appear to be hereditary, in some cases. Females are more subject than males, and repeated pregnancy seems to engender a predisposing condition.

*Termination.*—The fractured bones evince little or no tendency to the formation of callus; and as the deformity resulting from their bending increases, the patient becomes a wretched cripple, yet living perhaps for years. Ultimately, death ensues from sheer exhaustion; or, func-

tional disturbance, consequent on altered relations of the viscera or pressure from deformity, proves fatal.

*Treatment.*—No known medicinal agents have any curative efficacy. A generally tonic and nourishing plan of treatment may somewhat relieve the concomitant exhaustion of mollities ossium, and opiates alleviate the wearing pains. Posture, and mechanical contrivances, are also of some use in counteracting the progressive deformity, and rendering life more tolerable to the patient, when bedridden.

**FRAGILITAS OSSIUM.**—Brittleness of the bones is, pathologically, the opposite condition to Rickets; implying a superabundance of earthy matter in their composition.

Occurring as a natural change in the bones as life advances; it may also, at other periods, be symptomatic of cancer, syphilis, scurvy; and, probably, of other diseases of, or affecting, the osseous system.

#### TUMOURS OF BONE.

**Exostosis.**—*Structural Condition.*—Exostosis is an out-growth of bone, its texture therefore resembles either the compact or the cancellated structure of bone.

The *compact* variety, consisting of solid bone, is of small size, and is very hard—hence named *ivory-exostosis*. It is commonly situated on the flat bones, especially the cranium. This variety of exostosis—observes Mr. Paget—occurs in two forms. Some grow on the exterior of the bones of the skull, in smooth, spheroidal, or lens-shaped lumps, attached, commonly, by rather narrow bases. Others, which are usually of deeply lobed and nodular shapes, grow in the diploe, or the frontal or other sinuses, whence, as they enlarge, they project through the gradually thinned and perforated layers of bones that at first enclosed them. The former kind rarely increase to an inch in diameter; the latter may increase to many inches, and they commonly project into the cavity of the skull, as well as externally, or into the cavities of the orbits or any other adjacent parts.

The *cancellous* variety, consisting of the open medullary texture of bone, containing marrow, and invested with a very thin layer of compact tissue, is of considerable size, and yields somewhat under pressure. It is commonly situated on the shaft of a long bone; particularly the femur, on its inner surface, just above the condyle; the head of the tibia; or phalanges of the fingers or toes. Another very common situation—according to Mr. Holmes' observations—is beneath the deltoid muscle: but here I have never met with the cancellous variety of exostosis.

In both conditions, the structure of exostosis usually resembles that of the bones on which they, severally, grow. Exostosis generally occurs singly; but many may form, when they are usually symmetrical. This is particularly observed in the cancellous variety.

*Signs.*—The characters of exostosis are sufficiently obvious; a very hard, or a somewhat yielding, rather pedunculated tumour, immovable or nearly so; attached to the bone as an out-growth.

*Causes.*—The compact variety is attributed to syphilis, scrofula, or other diseases affecting bone, and which produce an out-growing hypertrophy of the compact osseous texture. The cancellous variety results from the ossification of an enchondromatous or cartilaginous tumour. It may, therefore, be said to be developed through cartilage;

while the ivory variety is rarely so produced. Age seems to have some causative relation to exostosis; both varieties commencing, probably, in earliest infancy.

*Course and Terminations.*—Both forms of exostosis are slow-growing, and particularly the compact variety; but the cancellous attains a far larger size. Both may undergo certain destructive changes; necrosis, or sloughing away from the bone, and occasion ulceration of the superimposed integument. Both also may occasion various functional disturbances by pressure. The situation of exostosis will very much determine these results. Thus, an ivory exostosis has projected into the orbit; or growing from the inner table of the skull has pressed upon the brain; or, from the pubic bone, has perforated the bladder.

*Treatment.*—Exostoses which remain stationary, or occur in certain situations, as the orbit, are better left alone. The danger also of exposing cancellated bone, should always be considered; diffuse suppuration and pyæmia being very liable to follow the operation of removal. Otherwise, an exostosis may be removed mechanically, by *excision*; or destroyed, by nitric acid or other strong *caustic*, applied to its exposed base.

Compact or ivory exostosis is often very difficult of excision. Several instruments should be provided; that one failing, another may prove efficient. A trephine, saw, chisel and mallet, or cutting pliers, are sometimes severally requisite to remove the little ivory-hard lump of bone. They all, in turn, failed in the hands of an expert operator—the late Mr. Keate—although employed perseveringly for nearly two hours. The exostosis having been removed down to its base, caustic may then be applied to destroy the remaining portion by exfoliation. Potassa fusa and nitric acid were thus applied successfully in Mr. Keate's case. Exostoses do not recur after removal; and, fortunately, even when the base of attachment is left, the tumour is not likely to grow again.

*ENCHONDROMA.*—In connexion with bone, enchondroma or cartilaginous tumour has already been considered, as being the most prominent part of the general pathology of this species of Morbid Growth (Chapter ii.); for it occurs principally in connexion with the osseous system. Enchondroma—or, occasionally, some other kind of growth—may be contained in the centre of a bone, and surrounded by an osseous shell or bony cyst; it is then sometimes designated “*bullous exostosis*,” especially by French Surgical authors.

*Treatment.*—Excision or amputation will be appropriate, according to the size and relations of the tumour.

*FIBROUS TUMOUR.*—The formation of a fibrous tumour in connexion with bone is far more rare than the cartilaginous tumour. It is, however, illustrated by epulis and fibrous nasal polypus; both of which are fibrous *out-growths*.

The *Signs* of any such tumour much resemble those of enchondroma; and their diagnosis is unimportant.

The *Treatment* is excision or amputation.

*CYSTS.*—Two kinds of cysts have been found in bone; the *serous* and *sanguineous*. Their pathology for the most part merges in the general history of these cysts (p. 85). They are *multilocular*, the cavities often communicating; and they are met with in the jaws or in the long bones—their shafts or articular ends. They grow to a large size, that of a cocoa-nut or fatal head. *Unilocular* cysts are also described by Nélaton as containing solid matter, of a fibrous or fibro-cartilaginous structure,

occupying entirely the cavity of the cyst. These are found in the same situations as the last, but grow to a less size. Cysts in bone occur mostly in adults.

*Signs.*—They produce an expansion of the surrounding osseous texture, and at length being enclosed in a thin lamellar capsule of bone, yield a crackling sensation under pressure with the finger and a deeper or more obscure elasticity or semi-fluctuation. Perforation here and there taking place by progressive absorption of the lamellar capsule, the enclosed tumour becomes more clearly perceptible. The superimposed skin yields before the increasing tumour; but without discoloration or any participation in the disease, and there is little or no accompanying pain. The tumour is thus plainly non-malignant in its development.

*Treatment.*—*Fluid* cysts may be laid open by removing a portion of the bone, by trephining or otherwise, and the cavity dressed from the bottom with lint. Granulation will then obliterate the cyst. *Solid* cysts must be excised, or recourse had to amputation; according to the size and relations of the cyst.

**CYSTIC TUMOURS.**—In bone, as in other parts, tumours occur, containing cysts. Fibro-cystic tumour of bone commences, apparently, in the cancellous tissue, and growing outwards, occasions fracture.

The *Signs* are those of cysts in bone; an elastic sensation or obscure fluctuation. The femur was the seat of the disease in four cases, one of which is related by M. J. Adams in the "Path. Soc. Trans.," vol. v., and the remaining three by Mr. Prescott Hewett, are appended to the report of that case. The absence of pain, integumental discoloration, and glandular swelling; distinguish this tumour and other innocent cystic tumours from Cancer. Amputation was followed by permanent recovery in the above cases.

**HYDATID-CYSTS** in bone, are interesting chiefly in relation to the *fluid* cysts, above described. The entozoon has been in all cases, the echinococcus or accephalocyst; except in one case, mentioned by Mr. Stanley, where the cysticercus cellulose was found in the interior of one of the phalanges. But hydatid-cysts are very rare; eight cases only being referred to in Rokitsky's work; to which a limited number of instances might be added. These cysts may be seated in a flat bone, as the skull or ilium, or in the expanded head of one or more of the long bones; cases of which are cited by Mr. Holmes.

The *diagnosis* with reference to ordinary fluid cysts, can scarcely be drawn. The cysts increasing in size, fracture occurs, as probably the first appreciable sign; and the bone remains ununited. This, however, is incident to other diseases of bone. A discharge of fluid containing entozoa would determine any question of diagnosis. This may occur spontaneously, or be obtained by puncture.

The *treatment*, also, is the same as for ordinary fluid cysts; but it will be advisable to destroy the interior of the hydatid cyst by freely applying nitrate of silver or other caustic.

**RECURRING TUMOURS OF BONE.**—The *Myeloid* form of Enchondroma, in connexion with bone, is sufficiently described in the general pathology and treatment of this growth.

Recurring *osteoid* tumour is illustrated by a series of three preparations in the Museum of the Royal College of Surgeons, to the remarkable history of which Mr. Holmes has called attention. A hard, and heavy, dry osseous substance formed around the ends of the femur and tibia, projecting into the knee-joint, extending far up the thigh and implicating

the popliteal artery, vein, and nerve, so as to cause œdema and severe pain. (Prep. No. 3244.) Amputation was performed at the thigh. The patient remained well for five years; then another osteoid tumour formed on the stump of the femur, accompanied with severe pain. Amputation was performed higher up. The tumour appeared to grow, not from the bone itself so much as from the periosteum, and enclosed the femoral artery. (Prep. No. 3245.) An interval of health again continued for two years; when another tumour formed about the stump, progressed upwards, out of reach of operation, and finally proved fatal, by inflammation and sloughing of its soft coverings, twenty-five years after the first appearance of the disease. The general health of the patient, a male, remained unaffected during the whole period. (Prep. No. 3245A.) Another, and very similar case, may be found in Mr. Paget's Surgical Pathology.

These cases of recurring osteoid tumours, certainly bear a remarkable analogy, in their course and tendency, to the recurring fibroid and fibro-nucleated tumours—varieties of fibrous tumour.

CANCER.—Each species of Cancer—*encephaloid*, *scirrhus*, *colloid*, and *epithelial* cancer, is liable to form in connexion with bone; but encephaloid is the most frequent. Like other diseases of bone, Cancer may affect the *substance* or the *surface* of a bone; in the one situation, it is known as interstitial or possibly central cancer, in the other, as periosteal cancer.

In the *substance* of bone, *interstitial* cancer occurs in the form of scattered nodules, having a whitish colour, and the consistence of scirrhus, or hard encephaloid cancer. The cancer-cell—so little absolutely characteristic of cancer—may be indistinguishable or absent. These nodules coalescing, form a mass, which occupies the cancellous tissue, and extends into the medullary canal. The bone surrounding such a formation is expanded and thinned or thickened; with osseous fibres traversing the substance of the tumour, radiating from its centre. It is situated most commonly, in the articular ends of a long bone, or in a flat bone, as the pelvis or skull. As affecting the whole bone, this condition of the disease is sometimes designated, *infiltrated* cancer of bone.

On the *surface* of bone, *periosteal* cancer forms between the bone and periosteum; rarely involving the one, while the other may sometimes be traced over the tumour. Osseous fibres radiate from the surface of the bone through the tumour; and a bony deposit forming a coral-like mass, often spreads around it. Periosteal cancer appears, usually, in the long bones, especially affecting their articular ends. The incrusting cartilage of the contiguous joint generally escapes, in both this, and the interstitial formation of cancer; although the disease may extend to the capsule.

*Osteoid* cancer is a term used to designate a further degree of ossification, than that commonly met with in interstitial and periosteal cancer-growths. This is analogous to the ossification of enchondromatous or cartilaginous, and fibrous, tumours. Osteoid cancer is described by Mr. C. H. Moore as being, in a well-marked case of the primary tumour, a large mass of the hardest enamel or ivory-like bone; the glandular disease is bony, though it may be less hard; and the disease disseminated in the soft internal organs, and protruding into the blood-vessels, is also in great part, osseous.

Any bone is liable to cancer-formation; but some are far more so than others. The femur and tibia are most subject to the disease, and particularly the articular ends of these bones at the knee-joint. Thus, of 20 cases of cancer of the long bones of the lower limb, 11 were situated near

this joint. The pelvis, spine, skull—especially the antrum and the humerus—are also seats of cancer.

*Signs, and Diagnosis.*—(1) Cancer in the *substance* of bone, produces expansion and an osseous tumour; but the nature of this tumour can scarcely be recognised at first. The enclosed encephaloid cancer is much harder than when this disease affects the soft parts. At length, the enclosing shell of bone yields, and the mass declares itself at once, or very shortly, as the tumour unrestrained, grows more rapidly. The ordinary characters of an encephaloid tumour become apparent; its soft consistence, lobulated contour, and large size; with purple discoloration of the skin, enlarged, ramifying veins, and pain throughout the course of the disease. Pulsation, of a thrilling or blowing character, may become perceptible, owing to enlargement of the vessels in the tumour, as it undergoes development. Fracture often occurs at the affected part. Glandular swellings and constitutional symptoms will confirm the diagnosis.

(2) *Periosteal* cancer presents a tumour of more clearly cancerous character, and it grows more rapidly, at an earlier period. The muscles attached to the bone often become extensively infiltrated with cancer-cells.

Thus may Cancer in, or on, bone, be recognised and distinguished from any other species of tumour. The diagnosis of malignant and non-malignant tumour of bone, lies, however, principally between *encephaloid* cancer and *enchondroma*. Here the presence, or absence, ultimately, of the signs which indicate an extension of the disease to the integument and neighbouring lymphatic glands, will mainly determine the question. Puncture with a grooved needle is also available as a critical method of examination, in this case, no less than in other doubtful forms of tumour. I was thus enabled to determine the nature of a tumour at the lower end of the femur close to the knee-joint; which in point of consistence and lobulated appearance, much resembled enchondroma. Amputation was performed, and the mass proved to be encephaloid.

*Pulsating* encephaloid may be distinguished from *aneurism* by the expansive, heaving character of the latter, as compared with the thrilling vibration of the former.

*Treatment.*—*Excision* will be appropriate only in cases of limited cancer-growth in, or on, bone; and when situated where the whole diseased portion can thus be removed. But under, apparently, the most favourable circumstances of limitation, the operation itself may prove most *perilous*. I once assisted my colleague, Mr. De Meric, in removing an, apparently, moveable tumour, the size of a small orange, and situated over one of the mid-ribs. But this little mass sprang from the bone, the rib readily broke, and the welling up of blood from the tumour—an encephaloid cancer—was so profuse, that the patient nearly died on the spot. He sank in a few days from hæmorrhage into the pleura.

*Amputation* must generally be resorted to. This operation should be performed in the earliest recognised condition of the disease, and certainly before any enlargement of the lymphatic glands has evinced the super-vention of systemic infection. Moreover, removal by amputation can only be effectual for the prevention of the recurrence of cancer, when the operation is performed high above the part affected so as to be entirely free of the seat of the disease. Hence, in *interstitial* cancer of bone, the line of amputation should be—not in the continuity of the bone—but above the next joint; and in *periosteal* cancer the line will be most

judiciously selected even higher up, above the origins of the muscles infiltrated probably by proximity to the disease.

**PULSATILE TUMOUR of bone, and OSTEO-ANEURISM.**—*Structural Conditions.*—A pulsating tumour in, or on, bone, may be—(1) a tumour, *not itself* pulsating, but in connexion with an artery which communicates its pulsations thereto; as, an enchondromatous, fibrous, or other tumour, thus connected; (2) a *vascular* tumour; usually cancerous, and particularly, encephaloid in the course of its development; (3) a *vascular growth* or erectile tumour of bone, resembling aneurism by anastomosis in the soft parts, and constituting *osteo-aneurism*. This last condition is very rare, if it exist at all; and the best authorities, such as Cruveilhier and Rokitsansky are agreed respecting the rarity of osteo-aneurism, and that most pulsating tumours of bone are highly vascular encephaloid tumours.

The situation of any such tumour is generally the *cancellous interior* of a bone, especially of the long bones, at their articular ends; as the femur, tibia, humerus, radius; also in the flat bones; as those of the pelvis and skull, and in the ribs.

*Signs, and Diagnosis.*—An enlargement of the bone, with a thrilling pulsation and bruit, are symptoms common alike to a highly vascular tumour, such as advanced encephaloid cancer, or aneurism by anastomosis. And, this pulsation subsides on compressing the main artery of the limb. But the persistence of a tumour, and its incompressibility, would be distinctive of a mass having formed independent of the blood-vessels, a *vascular tumour*, and not a *vascular growth* or enlarged congeries of vessels. The bony case, however, which encloses any such tumour renders this test inapplicable, until the bone yields and the mass protrudes on the surface of the bone. Or, compression of a main artery may be impracticable, owing to the situation of the tumour, as in the pelvic bones. Or again, the supply of blood may come from so many arterial branches, that it cannot be arrested by compression. A tumour pulsating in *connexion with an artery* is also distinguished in like manner.

Subsequently, the nature of the tumour will be still further declared by its more developed characters; encephaloid cancer, for example, enlarges rapidly, and involves the skin and lymphatic glands.

*Treatment.*—Having due regard to the almost exclusive cancerous nature of pulsating tumour of bone; *excision* must have the same restricted applicability as with regard to cancer of bone in general. This operation has failed in cases of cranial and scapular pulsating tumours.

*Amputation* is the only justifiable operation of removal, in other than the few exceptional cases alluded to. The more decidedly encephaloid the disease, the more appropriate will be this more sweeping operation. It should be performed as soon as the nature of the disease is declared, and the line of amputation be chosen above the joint nearest to the bone affected.

*Ligature* of the *main artery* leading to the part is said to have proved successful in some cases; but probably not in pulsating tumour of bone having an encephaloid character. Compression might be tried previous to ligature.

**DISEASES OF PARTICULAR BONES.**—**CRANIAL BONES.**—*Caries* and *Necrosis* of these bones are liable to occur, as one of the local manifestations of Scrofula or of Syphilis. Commonly affecting the arch of the skull, and particularly the frontal bone; the ethmoid and sphenoid bones do not escape. The temporal bone seems specially prone to scrofulous caries.

The *structural condition*, and *signs*, are both described under the

general pathology of Caries as affecting the *surface* of Bone, and of Scrofulous and Syphilitic Otitis, and *exfoliation*.

The *causes*, most frequently constitutional, are sometimes traumatic; as exfoliation resulting from a contused wound of the scalp, or other injuries of the head.

The *course* of either state of disease is important with reference to the probability of cerebral complications; meningitis with effusion, convulsions and coma, being apt to supervene and terminate fatally. Caries of the petrous portion of the temporal bone, as a form of Scrofulous disease, is more particularly dangerous. Ear-ache with chronic suppuration leads to perforation of the tympanum; the ossicula crumble, loosen, and are washed out by a profuse fetid discharge, exposing the dura mater continuous with the cavities of the ear. If the disease be not fatal, permanent deafness results.

*Treatment*.—The local measures for the removal of carious or necrosed portions of bone by operative interference, and the constitutional treatment of Scrofula or Syphilis, are in no way peculiar to the Cranial Bones.

DISEASES OF THE JAWS will be considered, under this title, in connexion with Diseases pertaining to the HEAD.

DISEASES OF THE SPINE.—See SPINE.

## JOINTS.

### CHAPTER XXXII.

#### INJURIES.—SPRAINS.—WOUNDS.—DISLOCATIONS.

SPRAINS OR STRAINS OF THE LIGAMENTS OF JOINTS.—These lesions essentially resemble similar injury of TENDONS [ch. xx.]. The *ankle* or *wrist-joint* is most commonly affected. Severe pain, possibly inducing syncope, is soon followed by swelling around the joint; succeeded by stiffness, and continued inability to use the joint. A very severe sprain, or its repetition, may leave the joint in a state of permanent weakness, and liability to dislocation. Or disease of the joint may ensue, in persons predisposed by any constitutional condition, as a rheumatic or gout diathesis. And it would seem that injury to a joint so alters its structural condition as possibly to induce disease under favourable circumstances; and perhaps after the lapse of a considerable period. Thus, Sir B. Brodie, shortly before his death, I believe, suffered from a malignant tumour of the shoulder, which was, apparently, referable to some textural disorganization consequent on dislocation of the joint some years previously.

The *cause* of sprain, is a violent and sudden twist or wrench of a joint, whereby the opposing ligaments are stretched or somewhat ruptured.

The *treatment* consists in an easy position and rest, warm or cold applications, according to the inflammatory character of the swelling and the feelings of the patient; followed by stimulating embrocations, and the support of a bandage, broad strips of plaster, or a starched bandage.

WOUNDS OF JOINTS.—A wound extending into a joint may, like other Wounds, be *incised*, *punctured*, *contused*, or *lacerated*; and the joint,

accordingly, is more or less opened, or extensively injured. But, the admission of air into the joint chiefly determines the importance of any such lesion; and thus the pathological condition of these different wounds must be estimated by this consideration. The extent of the synovial membrane, or the size of the joint should also be taken into account.

*Signs and Symptoms.*—The escape of synovia from the external aperture, or an exposure of the interior of the articulation; are the only pathognomonic or absolute signs of a wound into a joint. Synovial fluid is recognised by its translucent, viscid, albuminous character, resembling raw white of egg; the interior of a joint presents the additional characters of glistening synovial membrane and cartilage, and the peculiar disposition of the articular surfaces. But these appearances should be discovered by inspection, or gentle introduction of the finger; an exploring instrument might penetrate the synovial membrane, and cause a wound not otherwise existing.

Inflammation of the synovial capsule rapidly supervenes, presenting the usual appearances of synovitis, but distinguished by two peculiarities; the *intense* pain, and *more acute* constitutional disturbance. Suppuration also is almost inevitable, with hectic, and irreparable destruction of the articular surfaces constituting the joint; or pyæmia intervening at an early period, proves fatal. In two cases, under my care in the Hospital, wounds of the knee-joint exposing the articulation, both terminated in this way.

*Treatment.*—Preservation of the limb—without any operative interference—should always be attempted, in the first instance. But the probability of success will depend chiefly, on the nature of the wound, and the extent of the synovial membrane or the size of the joint. A small incised wound or puncture, in a small joint, as one of the finger-joints, allows of preservation with great probability of success; a large, open, and perhaps contused wound, in a large joint, as the knee, is almost surely fatal to limb and life. Among large joints, however, those of the upper extremity—the shoulder, elbow, and wrist, are, commonly, more favourably disposed, than in the lower extremity—the hip, knee, and ankle. To save a joint, the wound must be at once closed, thus to solicit union by primary adhesion. A pledget of lint or piece of isinglass-adhesive plaster, may be used for this purpose; or I would try the dressing with carbolic acid paste on tinfoil, according to Mr. Lister's plan under similar circumstances. Repression of inflammation can sometimes be accomplished by rest and cold evaporating lotions.

Synovitis having proceeded to suppuration—the synovial capsule having become converted into an abscess, the joint should be laid freely open by incisions, as advocated by Mr. Gay; and a position of the limb secured favourable for its utility, in the event of irreparable destruction of the articulation followed by ankylosis.

Destruction of the joint, without this issue, must be met either by *excision* of the diseased bone, or by *amputation* of the limb. The choice of these alternatives should be determined by a due consideration of the local and constitutional conditions. Fortunately, *traumatic* arthritis, as proceeding from the synovial membrane to the adjoining cartilages and bones, seldom engages these structures beyond the range of excision. But, the constitutional exhaustion may be so severe, as to compel recourse to secondary amputation, rather than peril life by the slow recovery consequent on excision. Or, amputation may become necessary,—and then without an alternative—*after* excision.

*Primary* amputation, it would thus appear, should not be resorted to in any case. But, in its preventive relation to pyæmia, more especially, it is questionable whether this operation might not be justifiable, occasionally. An open, and perhaps *contused*, wound, of a *large* joint, as the knee, represents conditions which may justify immediate amputation. In my two knee-joint cases life might, probably, have been saved by such timely intervention.

Fracture involving the joint, or dislocation, as complications, in similar cases, mostly demand immediate amputation.

*Wounds of Particular Joints* are to be regarded in accordance with the general pathology and treatment of this kind of Injury.

#### DISLOCATION.

**DISLOCATION.**—*Structural Conditions.*—Dislocation is a displacement of the articulatory portion of a bone from the surface on which it was naturally received; accompanied by more or less laceration of the ligaments or other surrounding structures. Dislocations differ essentially in

FIG. 155.

regard to the mode of their reparation, according as they are unaccompanied, or attended, by an open wound communicating with the dislocation; the one being termed *Simple*, the other *Compound*. *Complicated* Dislocation is also a recognised distinction, signifying the concurrent injury of some other part. But this is not an essential condition, as pertaining to Dislocation. *Congenital* Dislocation arises from malformation of the joint affected. In respect to the extent of displacement; dislocation may be *incomplete*, as hinge-joint dislocations not unfrequently are; or *complete*, as those of orbicular joints usually are (Fig. 155), this difference being due to the particular shape of the articular surfaces. The primary displacement is made more complete, especially in orbicular-joint dislocations, by tonic contraction of the muscles, subsequently.

*Signs.*—Dislocation is attended with a corresponding defacement or deformity of the *outline of the joint*; as represented by dislocation of the shoulder-joint, downwards into the axilla. (Fig. 156.) The natural prominences of bone near the articulation either disappear, or are less conspicuous, as the great trochanter at the hip-joint; or they may be more prominent, as the acromion, in dislocations of the shoulder. The *length of the limb* is altered, and especially if the dislocation be complete. Elongation, or shortening, is produced; according as the head of the displaced bone happens to be lodged below, or above, the level of the articular surface on which it naturally moves. The possibility of either, or of only the latter, alteration of length taking place, is determined by the form of the articulation. An orbicular joint allows of dislocation in any direction from its circumference; upwards, downwards, forwards, backwards. Hinge-joints cannot allow of displacement in more than three directions; backwards, forwards, and laterally, to the right or left. The *direction* of the dislocated bone, and thence of the *limb* below, is characteristic. Certain muscles being thrown out of action, by displacement of

the portion of bone to which they are attached ; others thus acquiring a mechanical advantage, preponderate. The natural balance of opposing muscles, as flexors and extensors, is lost, and the limb acquires that particular attitude to which the predominant muscles direct it. To these positive signs, may be added two negative ones; *immobility* of the limb

FIG. 156.

which gradually supervenes, in proportion to the tonic contraction of the muscles ; and also the *absence of crepitation*. Pain, and inability to use the limb, are *functional* symptoms of Dislocation, but of equivocal value for an early and exact diagnosis. [P. p. 173.]

*Diagnosis.*—The pain may be insignificant at first, before swelling supervenes ; and in oft-recurring dislocation, where the ligaments and muscles are weakened, and especially in an old feeble subject. The power of motion may be retained under similar circumstances, for the tonic contraction of the muscles is insufficient to fix the limb. But if both pain and powerlessness are present, they may each arise from other causes than dislocation ; from fracture, a bruise, or rheumatism. The *physical* signs of Dislocation, are, *severally, more* sufficient to determine the diagnosis, than in the case of Fracture. The signs alluded to are, each, in various degrees, invariably present, and are almost exclusively connected with Dislocation.

It is only as compared with Fracture in the neighbourhood of a joint, that Dislocation can be confounded. But, firstly, the outline of the joint is different, otherwise than in exceptional cases. Thus, dislocations of the hip-joint may be distinguished from fracture of the neck of the thigh bone, by this sign ; so also, dislocations of the shoulder-joint, as compared with fracture of the anatomical neck of the humerus. Then again, as to alteration of the length of the limb ; elongation is always peculiar to dislocation—shortening may, however, be due to unimpacted fracture with displace-

ment. Fracture may, thus, simulate dislocation upwards, in orbicular dislocations; or dislocation, forwards or backwards, in hinge-joint dislocations. It is, therefore, only between *ordinary* cases of fracture and *certain* dislocations, that the diagnosis by this sign is equivocal. The direction or attitude of the limb is always peculiar to dislocation. Lastly, the crepitation and mobility of fracture, are both absent with dislocation. So far, physical signs, severally, supply an exact diagnosis. As immediate signs, they are of equal value for an early diagnosis; excepting, perhaps, in regard to one physical sign—immobility of the limb. Tonic muscular contraction, whereby a dislocation becomes fixed, takes place slowly; and immobility, therefore, can scarcely be regarded as an early sign of dislocation. In one case, a dislocation of the femur into the foramen ovale was examined by Sir A. Cooper, a few minutes after the accident; the limb was still very moveable, and continued so for the space of nearly three hours, when it became fixed.

If then, the physical signs of Dislocation, are, severally more diagnostic than those of Fracture; *collectively*, they cannot fail to establish the diagnosis of this injury.

*Causes, and effects of Dislocation.*—Dislocation is produced, in general, by external force, suddenly applied. *Predisposing* causes are, however, very influential. Some such causes are functional actions depending on anatomical conditions; as the shape of the articular surfaces allowing a free range of motion, laxity of the ligaments retaining them, and the powerful action of many muscles on a long lever-like bone. All these predisposing conditions are combined in the shoulder-joint, and less so in the hip. Hinge-joints being more favourably circumstanced anatomically, are less liable to dislocation. Other predisposing conditions are acquired by disease; and these also have reference to the cartilage and head of bone, which may be destroyed by ulceration and caries; to the ligaments, as loosened by this process; or to those muscles which naturally aid in retaining the articular surfaces in apposition, but, which may have become wasted and enfeebled, or paralysed.

Dislocation itself operates as an internal cause of constitutional disturbance, by producing shock in a greater or less degree, followed by reaction; or, this, accompanied with shock, as prostration with excitement; which may be succeeded by Tetanus. [P. ch. ix.] But simple Dislocation is *essentially* local in its effects, and does not necessarily cause any persistent constitutional disturbance.

*Repair.*—The ruptured ligaments, and tendons if any be torn, are disposed to re-unite by primary adhesion; without inflammation. Lymph is effused which speedily passes into fibrous tissue, through the medium of nucleated blastema. Any superfluous reparative material, and the blood extravasated by the injury, are absorbed; and thus the concomitant swelling subsides. The joint is ultimately restored to nearly its originally perfect construction. This presupposes the previous *reduction* of the dislocation.

If the bone remain dislodged from its natural articulatory surface or cavity, then a *new joint* is constructed, the mechanism of which, however, is more or less complete, according to the kind of texture on which the bone has found a resting-place. If lodged on *muscle*, it gradually burrows for itself a convenient nest, the two surfaces become mutually adapted to each other, and, a capsular ligament being formed of condensed cellular texture, an imperfect joint is established. But if the displaced bone be lodged on *bone*, this loses its periosteum, and that its articular cartilage;

a receptacle is excavated suitable to the impression of the articular surface; a bony rim or lip is thrown up by the periosteum around the margin of this newly formed cavity; the surrounding cellular texture, moreover, becomes condensed into a capsular ligament, which further provides against any displacement; and thus a far more perfect joint is constructed. (Fig. 157.) In either case, the muscles which act on the dislocated bone retain it in its new position, and, becoming permanently shortened, their lines of action get accommodated to the displacement. The track through which the head of bone passed is now filled up with plastic lymph, and the ligaments, perhaps, have become adherent to the neck of the bone; the original articular cavity loses its cartilage and closes in, undergoing also partial obliteration by a dense fibrous deposit. This articular transformation is well shown in specimens—rarely procured—of unreduced dislocation of the hip-joint. Implying, as it does, an irretrievable sacrifice of the articular cavity, the work of destruction, in any case, proceeds very slowly; Nature effaces the original articulation reluctantly.

FIG. 157.

The *Prognosis* of reduced Dislocation is favourable, with regard to re-union of the ruptured ligaments, and the tendons if any be torn; their reparation by adhesion being subcutaneous, and not affected by exposure to the air as in the healing of an open wound.

But the prognosis must be determined by a due consideration of all those internal causes, which either aid the recurrence, or may prevent the original reduction of Dislocation; and which are, moreover, *persistent* in their tendency to perpetuate the displacement.

Causes of *recurrence* may be noticed first, they being among the conditions already mentioned as predisposing to Dislocation. Some of these conditions are, as we have seen, anatomical; a patulous shape of the articular surfaces, laxity of the ligaments, and a long lever-like bone, on which many muscles act. Hence dislocations of the shoulder-joint are specially apt to recur, and less so hip-joint dislocations. Hinge-joints are, anatomically, less disposed to re-dislocation. Other such causes are morbid conditions; ulceration of the articular cartilages, and caries of the adjoining bone, relaxation of the ligaments, a weakened or paralytic condition of the muscles. Of causes *opposing* reduction, may be mentioned, the anatomical shape of the articular surfaces; as the prominent rim of the acetabulum, in hip-joint dislocations, and the cup-shaped head of the radius which is locked in front of the humerus, in dislocation of that bone forwards. Any ligaments which may not have yielded with dislocation, seem to bind down the bone; as the first phalangeal bone of the thumb when dislocated upon its metacarpal bone. Tonic contraction of the muscles can scarcely be regarded as an unconquerable source of opposition; but the structural change of the muscles which accompanies their permanent shortening and functional adaptation, in unreduced dislocation, is a condition of resistance, not to be overcome judiciously by

forcible reduction; and less so in proportion to the duration of this condition. The prognosis is that of *unreduced* dislocation, with the formation of a new or substitute-joint.

*Treatment.*—After Dislocation, especially of the orbicular joints, the muscles which favour the particular displacement, draw the head of bone into its new position, and there fix it; but, this displacement, and subsequent fixation, are accomplished *gradually*. The head of the humerus, for example, having been displaced forwards, by the violence which caused dislocation; it is then drawn inwards, and eventually, there fixed. But, *immediately* after Dislocation, the muscles are always partially paralysed by the shock to the nervous system consequent on the injury, and for a short period they remain powerless. Subsequently, their tonic contraction comes into operation. Therefore, at the time of dislocation, and soon after, the displacement, caused by muscular action, can be easily replaced; and any resistance, of this kind, may be *partly* neutralized by a position suitable to the further relaxation of the antagonistic muscles. This then is the earliest condition of dislocation, ere the muscles complete the displacement; and this the most favourable opportunity for its reduction, when the muscles are as yet *powerless*. Thus, immediately after a dislocation of the femur backwards, Liston, having this opportunity, immediately reduced it, on the spot, without pulleys, or even the help of an assistant.

If Dislocation be overlooked or neglected, for a few hours, the muscles will have then become more immovably adapted to their new lines of action; subsequently, they become shortened also; a new joint is in process of formation; the track through which the head of bone has passed is occupied with plastic lymph; if the rent in the ligaments be small, this aperture tightly embraces the neck of the displaced bone, which becomes adherent and more fixed; and lastly, the natural articular surface or cavity gradually undergoes obliteration. Replacement is, at length, scarcely practicable, if possible, and certainly not to be accomplished without endangering many structures; muscles, nerves, vessels, and perchance the bone itself; nor without re-opening the track through which the head of bone had passed, and re-rupturing the ligaments; and even then only to find the natural articular cavity effaced or obliterated. Delay, therefore, proportionately precludes replacement by any conservative surgical interference.

The rules of treatment are precisely analogous to those relating to Fracture.

(1) *Coaptation* or replaced position of the displaced head of bone, in relation to its natural articular surface or cavity. This implies a *suitable position* of the limb, as far as *possible*; to relax the antagonistic muscles which, by their tonic action, retain the head of bone in a displaced position, and resist its replacement. But coaptation also implies, *extension* and *counter-extension* of the limb; sufficient only to bring the head of bone parallel to its natural articular surface or cavity; the *reduction* of dislocation. Coaptation is then readily effected.

(2) *Maintenance* of coaptation, during the reparative process of reunion of the torn ligaments, tendons, &c. This still pre-supposes a suitable position; not, however, with the view of relaxing such muscular contraction as maintains coaptation, but for the prevention of re-displacement by the spasmodic action of antagonistic muscles. But it also implies the employment of suitable *retentive appliances*; and both, to

ensure *rest*. This is, obviously, only the continued fulfilment, and completion, of the former rule of treatment.

The *Reduction* of Dislocation is a *process*; in this respect differing from the reduction of Fracture, which is readily effected. In Dislocation, however, reduction must be accomplished by retracing the displacement which has been caused by the muscles in operation; the head of bone being conducted, through the course it has thus taken, back to the point where muscular action began. Tonic contraction of the muscles will then effect coaptation. It is in retracing the *course* of displacement—the performance of reduction, no less than as regards the *timeliness* of Surgical intervention, that the guidance of pathology is chiefly experienced in the treatment of Dislocation. To facilitate reduction, muscular resistance is eluded, partly by undertaking reduction as soon as possible after dislocation, when the muscles are as yet inoperative; and partly by placing the limb in a suitable position, as far as possible, to relax the antagonistic muscles. The *semi-flexed* position, as nearly as it can be attained, is the happy medium, generally desirable for this purpose. In hip-joint dislocations, flexion of the knee relaxes the three ham-string muscles; while, for dislocations of the knee, the gastrocnemius muscle also, is thus relaxed. For shoulder-joint dislocations, flexion of the elbow relaxes the biceps muscle. And it should be re-

FIG. 158.

membered, that the flexor muscles are always stronger, and, therefore, more resisting than extensors. The resources for subduing muscular resistance will be noticed presently, in speaking of the act of reduction. *Extension* and *counter-extension* of the limb are necessary in all cases, and more especially for the reduction of ball-and-socket dislocations. The extending force may be either manual—as exerted by the Surgeon with an assistant or more; or mechanically applied, by pulleys. (Fig. 158.) Manual extension is less steady and less enduring; and as those who are so employed become fatigued, they relax their exertions, the muscles engaged in the dislocation regain their original supremacy and draw the bone back again to its former abnormal position; reproducing the displacement, and the work of extension has to be done all over again. Extension by means of pulleys is, however, apt to become too forcible, thereby endangering muscles, nerves, vessels, and even the bone itself; but force applied by this means can be better directed than that of personal strength. In like manner, counter-extension may be maintained either by an assistant or more; or by mechanical resistance, a cloth or strap being secured to some fixed point, as a staple firmly fixed in a wall. The relative merits of these two means of counter-extension also should

be estimated by the respective characters of the forces, which are thus applied. As a general rule, pulleys are required only to reduce hip-joint dislocations. When employed, precautions should be taken that the integuments of the part to which the force is applied, are not injured.

FIG. 159.

Extension may, therefore, be applied to the limb through a belt, padded with soft leather. If a strong woollen cloth be used instead, the noose should be fixed around the limb by the *clove-hitch* tie, which retains its hold securely, without tightening. (Fig. 159.) Besides this provision against strangulation, a damp cloth, under the noose, will protect the skin from friction.

To what *part* of the limb should extension be applied? On this point, opinions are divided, as with regard to fracture. Some of the most eminent French Surgeons have recommended extension to be made *indirectly*, from the distal extremity of the limb; from the wrist, in shoulder-joint dislocation; from the ankle, in that of the hip-joint. It is alleged that the advantage thereby gained

is twofold. The muscles are not excited to spasmodic action, as they would be were force directly applied to the dislocated bone; and that besides this negative advantage, there is also the positive advantage of

FIG. 160.

a longer lever, wherewith to act on the dislodged head of bone. The English School, represented by Pott and Sir A. Cooper in this branch

of Surgical Practice, and supported by equally distinguished Continental Surgeons, as J. L. Petit, Duverney, Malgaigne, and Callisen; have advocated extension *directly*, from the dislocated bone. Thus, from the arm, when the humerus is dislocated (Fig. 160); from the thigh, when the femur is dislocated. This direct application of extending force avoids endangering the intervening joints, and tells more effectually on the displacement. Certain it is also, that a long lever is not requisite for any truly Surgical purpose. If the muscles be relaxed, no such mechanical advantage can be necessary; if not relaxed, muscular contraction can be so directed as to eventually complete the reduction without the aid of a long lever. Moreover, assuming the obvious advantage of a semi-flexed position of the proximal joint below the dislocation; this position will necessitate the application of any extending force directly to the dislocated bone. Counter-extension is most effectual when applied as directly as possible, namely, from the surface corresponding to the dislocation.

Supposing counter-extension to be rightly adjusted, extension should be made first in that *direction* which the bone has assumed by dislocation. The head of the bone is thereby made to retrace its course, and is finally replaced without any additional laceration of the textures. Then again, the extending force should be equable, not jerking, and gradually increased; accompanied, of course, by counter-extension, equal, and in the opposite direction.

Any *voluntary* muscular resistance on the part of the patient, during reduction, is subdued by diverting his attention. A question now and then, as to how the accident happened, may answer this purpose, if no other; and by inducing our patient to speak, we overcome any advantage which the muscles attached to the thorax, would otherwise have, were the chest fixed, as when the breath is held. This point of practice is, obviously, important in reducing dislocation of the shoulder-joint. *Tonic* muscular contraction is most surely overcome by the slow inhalation of chloroform; but this should not be resorted to in the *first* instance. Supposing increasing extension prove ineffectual, and that any further degree of such force would, or might, endanger the muscles, nerves, or vessels; *then* only, in my opinion, is the administration of *chloroform* justifiable, for then only is the occasional peril of its action warrantable as our next resource. We thus steer clear of two risks; the former concerning the limb, the latter, the life. Any postponement of reduction, would not be sanctioned by pathology; for the muscles would become more unyielding, and the head of bone, more fixed, until indeed a new and moveable articulation was established, and the natural one effaced; a twofold condition which would utterly forbid even the attempt at reduction. But if *prior* to this result, we fail at the time of our first attempt, and followed up with the relaxing aid of chloroform; what then? I omit the objectionable measures formerly resorted to; nauseating doses of tartarized antimony, and the perhaps irrecoverable loss of the vital fluid by copious venesection, in the erect position and from a large orifice to speedily induce cerebral syncope. The *warm bath* may prove sufficiently relaxing; but this failing, we are compelled to accept the only alternative, that of waiting until the immediate consequences of extension have passed off, and then to renew it; aided by the repetition of chloroform, the warm bath, or both these relaxatives, successively. This second occasion, fairly tried, should be our last by increasing-extension; yet it is not our last resource. *Unreduced disloca-*

tions, of some duration, and not reducible by ordinary extension, prolonged even for an hour or two, have sometimes been reduced by *tiring* the antagonistic muscles; simply by attaching a trifling weight to the limb for a few hours. This tiring-extension is quite safe, as regards both limb and life, and would, therefore, whenever practicable, be far preferable to increasing-extension under the influence of chloroform; but, if it fails, the muscles will have gained considerable advantage by the further delay, and by the consolidation consequent on inflammatory effusion. While, therefore, tiring-extension might be a valuable *safeguard*, probably an assistant, in the intervals of a first and second attempt at reduction by increasing-extension, aided, if necessary, by chloroform; as an *extra resource*, it is most eligible in old dislocations, where that mode of reduction would be dangerous or useless. "The younger Cline, in this way, succeeded in reducing a dislocation of the shoulder which had been out for several weeks and could not be replaced in the ordinary way. Having fixed the shoulder, a brick, attached to the hand, was suspended over the end of the bed. On visiting his patient next day, the bone had returned to the socket."<sup>\*</sup>

In the course of extension, and especially towards its completion, it is the practice of some surgeons, to *rotate* the dislocated bone, so as to *forcibly* clear away any adhesions in the path along which the displaced head of bone should return home. But this forcible detrusion of any and every obstacle is prejudicial or unnecessary. It is neither conservative nor the teaching of pathology. Guided by a sufficiently exact knowledge of the relative position of the parts, as disarranged by the particular dislocation and as affected by the process of inflammation; the Surgeon is enabled to direct the bone aright in the path it *should* go—to retrace its course peacefully—without thus, as it were, knocking on the head, right and left, these supposed obstacles. And if such obstacles have become established, in an old unreduced dislocation, then indeed it is very questionable whether reduction should be attempted, and certainly not accompanied with the rupturing force of rotation.

*Coaptation*, following adequate extension, is the next, and final step, after reduction, which it may be said to complete. The displaced head of bone has been reduced, or brought back to that point where the muscles first began to operate, and where it was situated immediately after the displacement as effected by the violence which dislodged the bone. It stands on the brink of its natural articular surface or cavity; the one ready to regain, the other to re-establish, the articulation. This final step, it is now the duty of the Surgeon to *observe*, or to *undertake*, by coaptation—a manipulation analogous to the setting of fracture. Surgical assistance is needed according to the resistance offered by the shape and attitude of the two articular surfaces to be brought together. Rarely, the ligaments are obstacles; solely, or additionally. The head of bone may only need *guiding* to its proper place, into which the muscles, if not too much relaxed, will draw it; or, it may require to be *lifted* over the brink of the articular cavity, if this, its margin be prominent; as that of the acetabulum, in relation to dislocation of the head of the femur. Direct manipulation is, however, more generally necessary in the coaptation of hinge-joint dislocations; while, in ball-and-socket dislocations, the displaced bone is more usually guided into its hole, by properly

\* System of Surgery, Chelius, vol. i. p. 766, note by South.

directing the axis of the limb, towards the finish of extension. The ligaments scarcely ever resist. They are, in most cases, extensively torn; the capsular ligaments especially so. Any ligament peculiar to the joint, is also generally torn through, as the round ligament in hip-joint dislocations; but—according to the observations of Sir A. Cooper\*—if one such ligament remain entire, it may occasion difficulty in the reduction, as he experienced with respect to the knee and ankle joints. In dislocations of the latter joint, it is often necessary to twist the foot, in order to relax the untorn ligament, before reduction can be effected. In dislocation of the proximal phalanx of the thumb on the posterior aspect of the metacarpal bone, it may be necessary to *divide* subcutaneously, one of the lateral ligaments; the external being most easily reached. This operation was successfully practised by Liston,† in two cases; in an old man, much intoxicated, and a boy, after fourteen days' dislocation. In the latter case, the dislocation was reproduced accidentally, a week afterwards; but *then* the reduction was readily effected—thus showing that the resistance previously was unquestionably due to the undivided ligament. In all cases, coaptation should be guided by a due knowledge of the pathological conditions, and not effected by mechanical violence.

Coaptation is announced by a snap, a jerk, or sensation of something having given way; this being the signal that the muscles have done their duty by drawing the head of the bone home. If, therefore, the muscular system be paralysed, as under the influence of chloroform, or if the particular muscles engaged be weakened by prolonged extension, or extension be overpowering at the time of coaptation; in either case, the usual signal cannot be given. The Surgeon will wait in vain for any such announcement of coaptation, and he cannot reasonably expect this evidence of its having taken place. But the limb immediately assumes its natural length and attitude, as in repose; and the natural *contour* of the joint is recovered. The latter sign is the one most available in practice; for, the natural length and shape of the limb cannot be compared otherwise than by suspending extension, a cessation of effort which would at once undo all that had been gained, if coaptation be not accomplished. The natural *mobility* of the limb is immediately regained with coaptation; and this sign, *coupled* with the anatomical characters just mentioned, plainly declare that the natural articulation is restored.

Being thus assured of this event, the Surgeon need do but little more. Muscular contraction, having finally brought the bone into place, retains it there. Unlike fracture, the reduction of which is accomplished easily, but maintained only by watchful care; dislocation is reduced only by watchful care, after which, the muscles take care of the joint.

To *maintain coaptation*, it is necessary only to fix the limb, and in a suitable position for the relaxation of any muscles which by their action might re-dislocate the bone. This indication is easily fulfilled by securing the limb with a bandage; the arm to the chest, the leg to its fellow. Position and immobility are the more requisite on behalf of shallow joints, and if the ligaments are naturally loose; both of which conditions characterize the shoulder-joint. The twofold precaution of position and immobility is yet more necessary on behalf of *any* dislocation; when the muscles which usually prevent its recurrence, are themselves naturally

\* Dislocations and Fracture of Joints.

† Practical Surgery, 1846.

flabby and weak, or have been weakened by the dislocation, and by the extension necessary for its reduction. If, in such case, the limb be not securely fixed and supported in a suitable position; it may re-dislocate itself, not so much by the action of antagonistic muscles, as by the mere weight of the limb.

*Rest* of the limb, thus retained in position, will also favour the subsidence of any inflammation which may have supervened. But, the inflammation being subcutaneous, it terminates in resolution, very rarely in suppuration. Any so-called antiphlogistic treatment, therefore, is as seldom necessary; certainly not of a constitutional character, and locally only, by the application of a cold lotion in the first instance; with subsequently friction daily to revive the dormant muscles. Ample time must be allowed for firm re-union of the ligaments or other lacerated textures; failing which, the joint will be permanently weakened and ever liable to re-dislocation. On the other hand, judicious exercise of the joint, by passive motion occasionally, will prevent the tendency, otherwise, to some degree of ankylosis and permanent stiffness; with the irrecoverable loss of muscular power in the limb.

**COMPOUND DISLOCATION.**—*Structural condition, and Diagnostic characters.*—Compound Dislocation is, essentially, Dislocation, with a wound in the skin communicating; thus exposing the injured joint, however indirectly, to the action of the air. The structural disorganization as regards the state of the joint, is the same as in simple dislocation; but compound dislocation is usually accompanied with more severe contusion or laceration of the surrounding soft textures. This condition, coupled with that of the aperture externally—which is also contused or lacerated; together form a Contused or Lacerated Wound, connected with, and around, a Dislocation.

The *Signs* of this injury are the same as those of simple dislocation, with the additional and distinctive character of an external irregular wound. In short, both the condition and characters are those of simple Dislocation, *plus* those of contused or lacerated Wound.

Compound dislocation occurs most frequently in the ankle-joint; occasionally in the knee and elbow; rarely, in the shoulder; and very rarely, in the hip-joint.

*Causes, and Effects of Compound Dislocation.*—Here also, the pathological history is that of simple dislocation, with certain peculiarities superadded. Generally speaking, the dislocated bone, having passed through the adjoining soft parts, in the direction of the displacement, and come to the surface, it protrudes through the skin; and thus the wound is an extension of the injury from *within*. But, in some cases, external violence is the cause of the wound in the skin and subjacent soft parts, as well as of the connected dislocation; which may then be regarded as produced by an extension of the injury from *without*. In the one case, the force is applied indirectly, to the bone at some distance off, and the injury is more a laceration, and less extensive; in the other case, the force is applied directly to the joint, and the injury is more a contusion. In both cases, the lacerated or contused textures are damaged beyond the apparent extent of injury; and the shock to the nervous system is more severe than with simple dislocation, owing to the greater damage to the soft parts, including nerves.

Tetanus is, perhaps, more likely to occur than after a contused or lacerated wound alone, and especially if the compound dislocation

be that of a ginglymoid joint, as of the thumb. Injuries of unyielding fibrous or ligamentous textures are, generally, prone to induce Tetanus. [P. p. 442.]

The textures injured, being in a state of disintegration, die, at least to some extent around, if the wound be allowed to remain open. This purely *traumatic* gangrene is the same as that caused by a lacerated or contused wound. Limited, therefore, to the part injured, and defined, eventually, by a line of demarcation between the living and dead textures; the gangrene is also immediate, if the injury itself be severe.

*Course and Terminations.*—Inflammation supervenes, followed by suppuration, often profuse, and partial sloughing; or gangrene, possibly, on a larger scale. Yet this also is limited to the seat of injury. Ultimately, compound dislocation, when reduced, not unfrequently undergoes reparation; the torn ligaments and tendons becoming reconnected, and the wound closing up by the healing process of suppurative granulation and cicatrization.

*Spreading gangrene*—due to some morbid condition of the blood—is only contingent, occasionally, on compound dislocation; just as it may be associated with compound fracture, and with contused and lacerated wounds. The phenomena of this species of gangrene were described under the last-named form of Injury.

The *Prognosis* of Compound Dislocation, as gathered from the foregoing elements of its natural course and tendency, is far less favourable than that of simple Dislocation. An *open* wound, communicating with the joint, as compared with subcutaneous laceration of the soft parts, is one unfavourable ground of prognostic distinction. Scarcely less so, is the *greater extent* of their laceration, usually, in compound Dislocation, especially if produced by direct violence. [P. p. 724.] *Spreading gangrene* is an adventitious condition, but as implying the co-operation of a constitutional cause, it has a most unfavourable significance. [P. p. 737.]

*Treatment.*—The same rules of treatment are applicable as for simple dislocation; but, certain particulars, having reference to the special pathology of compound dislocation, are peculiar to its treatment.

*Reduction* of the displacement may present special difficulties. Thus, if the bone *protrude*—Excision is preferable to violent efforts at reduction. The head of the astragalus has been removed, when, by dislocation forwards, it protruded and could not be returned.

*The Wound.*—Reduction having been accomplished, and the limb retained in a suitable position—to prevent the recurrence of dislocation—by appropriate bandaging or apparatus; the treatment peculiar to *compound* dislocation is that relating to the wound, and state of the soft parts involved. The *primary* indication is to close the wound, with the view of soliciting its union by adhesion, and thus convert the dislocation into a simple one. For this purpose, a pad of lint—soaked in blood from the wound, as formerly practised, or better, simply wet lint, or soaked in carbolic acid solution, should be applied over and around the wound—so as entirely to exclude the air. But—subsequently—watching the progress of the case; when primary adhesion becomes obviously impossible, the attempt should be forthwith discontinued, in order to give free vent to matter, during the process of suppuration. *Early* solicitation of healing by primary adhesion, and *timely* abandonment of the attempt, in favour of suppuration, as soon as this event occurs, or is inevitable;

constitutes a compromise, which overrules any objection as to the *probable* failure of the one, and the supervention of the other. It may secure the advantage, otherwise forfeited, of then having to deal with only a *simple* Dislocation.

In the event of Suppuration ; early, free, and dependent *incisions* are indicated, for the same reasons, as in compound fracture ; and a poultice, or spongio-piline soaked in warm water as a fomentation, is now the appropriate application ; to be exchanged for light water-dressing, or with carbolic acid solution, when the continuance of warmth with moisture would only sodden and relax, and when the wound is granulating. The same *hygienic* and *medical* treatment also, as for compound fracture, will prove efficacious in sustaining the system under the *hectic fever* and exhaustion consequent on prolonged and perchance profuse suppurative discharge, and in overcoming the typhoidal fever induced by gangrene or sloughing.

*Amputation*.—The “question of amputation,” depending upon the supervention of either profuse suppuration or gangrene ; the *propriety* of this operation is determined by pathologico-anatomical conditions parallel to those of compound fracture. (1) *Primary* amputation, only when the

FIG. 161.

whole substance of a limb being involved by compound dislocation, the limb itself is already, in the first instance, virtually lost, and life as inevitably endangered. Such was the condition of compound dislocation, represented in (Fig. 161), the integuments having been removed from the limb to display the various kinds and extent of lesion. Unique, as a new form of elbow-joint dislocation, by dislodgment of the radius and ulna outwards and *upwards* on to the external ridge of the humerus above the condyle, the forearm had thus undergone an “external latero-angular dislocation.” The relative position of the bones, and thence the peculiar appearance of the joint externally and configuration of the limb, are more particularly described in the Brit. and For. Med. Chir. Rev., January, 1866. As justifying amputation—the lesions *co-existing* were these. A large lacerated wound about the middle of the forearm in front, exposing the muscles and a portion of both bones, with the interosseous membrane. All the flexor muscles, superficial and

deep, were torn across, partially or entirely, sparing their tendinous and aponeurotic portions, which appeared deep in the wound as so many shreddy strings from which the muscular substance had been raked off. All the vessels and nerves, however, excepting, of course, their muscular branches, had escaped rupture; the ulnar nerve, the inferior profunda artery accompanying it above the joint, and the ulnar artery in the forearm, the median nerve with its interosseous branch and the corresponding branch of artery, and lastly, the radial artery and nerve. But the skin was almost completely detached from the sheath of the muscles on the front and back of the forearm, and some way above the joint. The large tract of subcutaneous cellular texture thus disorganized was infiltrated with blood, not discernible through the skin, which appeared unbruised. A small contused aperture just above and behind the inner condyle communicated directly with the joint, constituting a compound dislocation. This extensive injury was caused by severe contusion and a lacerating wrench between the buffers of two railway carriages. (2) *Secondary* amputation, when the extent of damage done by the injury being itself partial, the supervention of profuse suppuration or gangrene is only proportionately probable; and the limb, therefore, not inevitably lost, nor the life perilled. Such postponement of amputation is justifiable to give the limb its chance of preservation by delay; while the preservation of life is provided for by timely amputation, when the adverse circumstances, alluded to, actually supervene.

The rules laid down in surgical works, with reference to the *extent* of injury, are not the expressions of a sufficiently accumulated pathological experience, in different doubtful cases; and they overlook the necessarily unknown capabilities of reparation in different individuals. Cases occurring, from time to time, which have proved exceptional to any such rules, suggest the all-important consideration; in how many more cases might limbs be saved which are thus sacrificed surgically?

No extent of injury, as to the vessels, nerves, muscles, and integuments—short of the whole substance of a limb being involved—in connexion with compound dislocation, can be said to absolutely prohibit the attempt to preserve the limb, in the first instance.

Thus, compound dislocation of the knee-joint, was pronounced by Sir A. Cooper to be a condition of disorganization which imperatively demanded primary amputation. Exceptions, occasionally, have since disproved that dictum, in this form of injury. In the case of a boy, nine years of age, at the Westminster Hospital, Mr. White succeeded in saving the limb, by sawing off the condyles of the femur and reducing the bone. In the ankle-joint the end of the tibia may be removed and reduction accomplished; a proceeding which I remember Mr. Liston advocated nearly a quarter of a century ago. A person jumps out of a carriage behind, while the horse is running away, and alighting on his feet, the tibia of either leg may be driven through the integuments and, perhaps, come in contact with the earth. Removal of the bruised portion of bone, will facilitate the reduction, and has proved successful in preserving the limb. Dislocation of the astragalus, in like manner, may be similarly treated. *Excision*, indeed, bids fair to surpass amputation in other compound Dislocations.

COMPLICATED DISLOCATION.—Dislocation may be complicated by association with the laceration of *muscles* which are put upon the stretch; as

the pectineus and adductor brevis, by dislocation of the thigh downwards into the thyroid foramen; even their unyielding *tendons* are sometimes ruptured, as the sub-scapularis tendon, by dislocation into the axilla. *Large blood-vessels* occasionally share the same fate, accompanied with hæmorrhage and livid swelling; a *main nerve* also may be torn asunder. *Fracture* of the shaft or of the head, of the bone dislocated, is another complication. This is more likely to occur in dislocation from direct violence; as by a fall on the hip or shoulder, the neck of either bone is perilled; the olecranon also may be knocked off; the bulky head of the tibia shattered; or the tarsal end of the tibia broken and bruised. Thus, then, all the parts *around* a dislocation are liable to be involved in the injury. But, obviously, none of those special injuries to internal organs can occur, which may complicate the Fracture of certain bones. Respecting *morbid conditions*; local diseases—*i.e.*, of the joints themselves, may predispose to dislocation and thence to its recurrence, by previous disorganization of the joint affected; a parallel kind of complication to that of fracture from disease of the bone. So also, the diseased condition of the joint is frequently a local *manifestation* of some blood-disease—*e.g.*, syphilis or scrofula, as a constitutional cause, rather than of traumatic or local origin. Whenever dislocation from disease of the joint has the former mode of origin, the reparative process is proportionately slow and uncertain; the more so when the constitutional disease is actually in operation.

Of all these complications of Dislocation; those which are combinations of other forms of *injury* therewith, have been *already* noticed in connexion with compound Dislocation; while predisposing diseases of the joints, will be taken in relation to Unreduced Dislocation.

*Treatment*.—Both the general considerations of pathology, and the corresponding Rules of Treatment, pertaining to Complicated Fracture, are applicable also to Complicated Dislocation.

1stly. If any *morbid condition* be in operation, locally or constitutionally, the treatment must be entirely *subject* to such *causative* condition, as connected with the Dislocation. 2ndly. If there be any *injury additional* to Dislocation; the treatment of the *dislocation* may be of entirely subordinate importance, even although it be, as in many such cases, severely compound.

UNREDUCED DISLOCATION and FALSE-JOINT; CONGENITAL DISLOCATION.—These pathological conditions may be taken consecutively; the one as the result of neglected or possibly, irreducible Dislocation, the other, as being irreducible or incapable of continued reduction, owing to some congenital malformation. Both are supplementary to the pathology and treatment of ordinary Dislocation.

UNREDUCED DISLOCATION, and FALSE-JOINT.—*Structural Condition*.—The alterations of structure consequent on unreduced Dislocation are, the formation of a new joint, the obliteration of the former or natural articulation, and of the track through which the head of the dislocated bone passed to its present locality.

The new *joint* is more, or less, perfectly constructed. If the displaced bone be lodged upon *muscle*; it gradually burrows for itself a convenient nest, the two surfaces become mutually adapted to each other, and a capsular ligament being formed of condensed cellular tissue, an imperfect joint is established. But should the bone have found a resting-place on *bone*, this, by absorption, loses its periosteum, and that, its articular cartilage; a receptacle is excavated suitable to the impression of the dis-

placed articular surface; a bony rim or lip is thrown up by the periosteum around the margin of this newly formed cavity, the surrounding cellular texture, moreover, becomes condensed into a capsular ligament, which further provides against any displacement; and thus a far more perfect joint is constructed. (Fig. 162.)

FIG. 162.

A porcellanous deposit takes the place of cartilage, on the head or surface of the dislocated bone; or instead of this "*eburnation*," an imperfect fibro-serous surface or synovial capsule may be formed. (Hamilton.) The *natural articular cavity*—whence the bone was dislodged—loses its cartilaginous investment, and closes in. It is, at length, partially obliterated by a dense fibrous deposit. (See Fig.) So also is the *track* in the textures, through which the bone had passed.

Associated with this articular transformation, are certain accessory, but somewhat accidental changes, in relation to the ligaments, muscles, and tendons.

The *ligaments* perhaps become firmly adherent to the neck of the bone, thus further opposing its reduction, and if the rent be small through which the bone escaped, it may be tightly embraced. This is more apt to occur in a capsular ligament. Other ligamentous conditions are peculiar. The orbicular ligament around the neck of the radius may have been carried away entirely by dislocation of this bone, and be firmly attached at both ends to the humerus. A specimen of this kind is preserved in the museum of St. George's Hospital. The *muscles* which act on the displaced bone become permanently shortened, while their lines of action get accommodated to the displacement, and help to retain the bone in its new position. Or if any tendons were partially or entirely torn across by the violence of dislocation, they may have acquired new attachments, and such as are mechanically unadapted to the action of the muscles. A ruptured tendon sometimes forms a band of adhesion between the bones. In one instance,\* the tendon of the brachialis anticus muscle, having been torn off the coronoid process of the ulna, which was dislocated backwards into the olecranon fossa; this tendon became firmly united both to the

\* Specimen of dislocated elbow. Museum of St. George's Hospital. T. Holmes.

trochlear surface of the humerus and to the ulna below its original attachment, forming a kind of soft ankylosis between them. A tendon thus attached, is unfavourable to the action of the muscle connected therewith, yet its attachment aids in rendering the dislocation irreducible. Bony nodules form, occasionally, in the tendons around the seat of dislocation. Lastly, in these general changes, should be noticed the important one of adhesion sometimes having taken place between a large artery and the capsule or periosteum of the displaced bone.\*

All these structural alterations take place very slowly. The destructive changes, implying an irreparable sacrifice of the articular cavity, Nature reluctantly obliterates it, and with it the opportunity for reduction; only when long disappointed by delay and wearied by the lapse of time. The reparative alterations—those pertaining to the formation of a new joint—are most complete in ball-and-socket dislocations, as the hip-joint; the compensatory substitute for any hinge-joint is far less complete. In some such instances even, bony ankylosis is the result.

The *Diagnostic Signs* of unreduced Dislocation, and of the construction of a new joint, are; the physical signs of dislocation, *coupled* with restoration, more or less entirely, of the functional use of the limb or part. The characteristic alterations, in the form of the joint, length of the limb, and direction of its axis, still remain; while the power of using it is regained, and proportionately as the new articulation is perfectly finished off. Hence, this restoration of function is, at length, far more thoroughly established in unreduced Dislocation of a ball-and-socket joint, than in that of a hinge-joint.

*Treatment.*—The question of *interference* should be determined by the *mobility* of the new joint. (a) When freely moveable, the natural articular cavity or surface is probably obliterated; the processes of construction and destruction having proceeded simultaneously and correlatively. Hence, the indication is, *not* to interfere, to leave such an unreduced dislocation alone; any attempt at reduction being useless or worse. Under these circumstances, reduction has, indeed, been effected, but with great injury to the limb, and even with a fatal result. In one such case, that of a dislocated shoulder, reduction was followed by great swelling of the arm, a tumour formed in the axilla, which, at the end of thirty-eight days, burst with alarming hæmorrhage. Ligature of the subclavian artery fortunately saved the patient's life.† In other cases, suppuration in and around the joint, and gangrene of the limb, have been known to occur.‡ (b) When the action of a new joint is less easy, and less efficient; reduction of the dislocation may be *attempted*, and with successful issue to limb and life.

The *kind* and *amount* of extension, are, however, features in the treatment, worthy of special attention. Extension, gradually increased, and continued for perhaps some hours, or renewed daily, is necessary; to overcome the resistance of the shortened muscles, any adhesions of the tendons or ligaments, and to extricate the bone from its new articular adaptations. But, it should ever be remembered that, possibly, more than these *mechanical* obstacles to reduction, exist. There is always some risk of rupturing any blood-vessels which may have become adherent. Yet this is an accident which cannot be foreseen, otherwise than

\* Op. cit., Hamilton, 1860, p. 492. † Med.-Chir. Trans., 1846, vol. xxix. p. 25.

‡ *Traité des Fractures, etc.*, Malgaigne, vol. ii. p. 143.

by observing the general rule laid down respecting any surgical interference. Of course, reduction should be conducted under the influence of chloroform.

The *extreme periods* of unreduced Dislocation, within which limits reduction is practicable, with safety to the limb and life of the patient; can scarcely be determined by experience. Nor is this question of much practical importance, considering the functional conditions, already mentioned, which should guide the Surgeon. Successful results have been obtained at extreme periods, varying from a few days to many months, and even beyond two years! In a dislocation of the *elbow*, backwards, unreduced for six months, Mr. Darke\* continued extension with pulleys during eight hours and a half, when the bones returned to their proper situation. Three other cases of this date were successful in the hands of Gorre and Gerdy.† A dislocation of the *shoulder*, unreduced for six weeks, was overcome by Mr. Mash,‡ in the Northampton Infirmary, by extension at intervals with *pulleys*, during eight hours. A dislocation of the head of the *radius* forwards, of twenty-five months, in a child nine years old, was reduced by Dr. Stark;§ extension being repeated daily for twenty-two days, consecutively.

This is, I believe, the longest period at which such extension has been successful, in unreduced dislocation of *any* joint in the upper extremity. *Manual* extension has proved sufficient in some cases. Thus, I reduced a dislocation of the *radius backwards*, of ten weeks; the adhesions about the head of the bone audibly giving way. In the lower extremity, the periods of limitation have been much less, with regard to the *hip-joint*. In two instances, dislocation of the femur on the *dorsum ilii*, has been reduced after the lapse of six months. In both, reduction was effected by "manipulation;" the one,|| under the influence of chloroform, the other,¶ without; but in this case the patient, a boy, was feeble and the muscles flaccid. In both, the results were successful; the limb recovering its functions and the muscles regaining their bulk and strength. Respecting the *hip- and shoulder-joints*; Sir A. Cooper's large experience led him to select two months in the one case, and three months in the other, as the extreme periods at which reduction can be *safely* accomplished.

Any *opposing* tendons, ligaments, or adhesions, suggest the propriety of a previous accessory operation; that of dividing them, subcutaneously. Simple as this may appear, it is not always practicable, with a fair degree of safety to the part, and even to the life of the patient. Yet there are successful results on record. Thus, in dislocation of the thumb backwards upon the metacarpal bone, reduction may be impossible, unless by subcutaneous division of the lateral ligaments. Sir Charles Bell first proposed the operation in this case, and it has since been successfully practised by Liston, Reinhardt, Gibson of Philadelphia, Parker of New York, and other Surgeons. Lizars and Syme advocate this practice in certain instances. An unreduced dislocation of the shoulder-joint, of two years' duration, was overcome by Dieffenbach, in like manner. In one instance also, an old dislocation of the elbow, which still resisted after

¶ Fractures and Dislocations, Hamilton, 1840, p. 663, Philadelphia.

division of the tendons and ligaments, was reduced by dividing the adhesions. M. Blumhardt\* made a longitudinal incision on either side of the joint, laid open the capsule, freely divided the adhesions, and replaced the bones. The limb is said to have recovered its natural mobility, and the patient resumed his occupation as a carpenter.

In cases such as these, the *periods* after dislocation, at which operations have proved successful, are comparatively unimportant; for the difficulties of reduction being thus overcome, the operation *itself* is the only important consideration—*i.e.*, as to its propriety and practicability.

CONGENITAL DISLOCATIONS.—The whole pathology of “Dislocations existing at birth,” requires further investigation, in respect to their structural conditions, causes, and vital history.

Congenital Dislocations are, apparently, of three kinds: (*a*) Physiological dislocations; or those resulting from an original defect in the germ, or from an arrest of development. (*b*) Pathological dislocations; or those resulting from some lesion of the nervous centres, from contraction or paralysis of the muscles, laxity of the ligaments, hydrarthrosis, or some other diseased condition of the articulation. (*c*) Mechanical dislocations; or those resulting from some peculiar position of the fœtus in utero, violent contractions or constant pressure of the walls of the uterus, falls and blows upon the abdomen, and unskilful manipulation of the child in delivery. These might be termed traumatic dislocations. Probably all the joints are liable to congenital Dislocation, in some form or forms; and with regard to most of the joints, this kind of lesion has already been established by dissection. Hamilton has collected many such instances; but it appears to occur most frequently in the hip and shoulder-joints.

The *Treatment* of Congenital Dislocation is *generally impracticable*. What to do may be obvious; the removal of any one, or more, of the known conditions which originally produced the dislocation; but how to do this successfully, may be impracticable, owing to those conditions being, generally, defective forms of structure, which, in producing, also perpetuate the recurrence of dislocation. Persistency of the cause, or causes, in operation, thus renders these lesions mostly incurable.

The fact of congenital dislocation of the *hip* occurring, was known to Hippocrates, and expressly noticed in his work, “*De Articulis*.” Other early authors, Avicenna, Paré, and Kerkring, also mention such dislocation of this joint; the latter recording an example verified by dissection. Subsequently, Chaussier† recorded a congenital dislocation of the *shoulder*, and another of the *hip*, both in the same infant. Paletta, of Milan, added to the cases then known;‡ and, in his hands, the injury first assumed a pathological character.§ But it was reserved for Dupuytren|| to investigate congenital dislocations, enlightened by pathology and physiology. Among other special authorities, the following have contributed the most valuable sources of information:—Breschet,¶ Caillard-Billionnière,\*\* Lehoux,†† Sandiforte,‡‡ Duval and Lafond, Humbert and

## CHAPTER XXXIII.

### SPECIAL DISLOCATIONS.

DISLOCATIONS OF THE LOWER JAW.—*Structural conditions.*—Complete dislocation on *both* sides consists in the dislodgment of both condyles from the glenoid fossæ, and their displacement forwards, in front of the anterior or transverse root of the zygoma, on either side; the coronoid processes thus being brought forward, and corresponding to the under aspect of the malar bone, on either side. (Fig. 163.) Similar dislocation on *one* side only, represents the same altered articular relations of the condyle, on that side; with a twist of the jaw to the opposite side. *Partial* dislocation, or subluxation of the jaw, is, apparently, a displacement in relation to the inter-articular cartilages; the condyles slipping forwards in front of these cartilages, on both sides, or on either side alone. Bilateral dislocation occurs in about two of every three cases. Partial dislocation happens, comparatively, seldom.

FIG. 163.

*Signs.*—Certain obvious and characteristic signs attend dislocation of the jaw. The mouth is open, the jaw being drawn down by the action of the genio-hyoid muscles, and the lower teeth project in front of the line of the upper teeth. This open-mouthed appearance is more conspicuous at first, the distance between the teeth extending sometimes to an inch and a half; subsequently the jaws become more closed, but the coronoid processes, hitching against the malar bones, mechanically oppose any nearer approximation. Deglutition and speech are interrupted, the lips moving when the person attempts to speak and the saliva dribbling

over the chin. The cheeks are stretched and flattened, and the angles of the jaw directed somewhat backward towards the mastoid process of the temporal bone, on either side; a depression can be felt in front of the external auditory meatus, corresponding to the natural situation of

FIG. 164.

the condyle, and an oblong prominence in the temporal fossa with fulness of the masseter muscle. (Fig. 164.) Dislocation on *one* side only is denoted by the same signs; but in a lesser degree, and one-sided, the jaw being twisted somewhat to the opposite side, though this alteration may be scarcely appreciable. A depression can always be felt in the proper situation of the condyle, and not on the other side.

Partial dislocation presents similar signs, but they are still less perceptible, and perhaps recurring, the condyle slipping to and fro.

*Causes.* — *Muscular action* would seem to be the usual cause, in the act of opening the mouth widely; as in laughing, gaping, violent declamation, yawning, or an attempt to take too large a bite.

The condyles moving forward on the transverse root of the zygoma on either side, are dislocated by the action of the external pterygoid muscles; the genio-hyoid muscles then depressing the jaw. *External violence* is an occasional cause, as in tooth-extraction, or the forcible introduction of something into the mouth. Sir A. Cooper records such a case; two boys were struggling for an apple, and the one in attempting to thrust it into his own mouth, dislocated his jaw. *Age* would certainly seem to have some predisposing influence; complete dislocation occurring very rarely in infancy or advanced life, owing probably to peculiarities in the form of the jaw at these periods. Nélaton attributes its greater frequency in middle life, to the length and anterior inclination of the coronoid process. *Women* also seem more liable than men; and to partial dislocation in particular, which arises probably from relaxation of the ligaments of the jaw.

*Unreduced* dislocation of the jaw undergoes changes, whereby the jaw becomes approximated to the upper and its anterior projection is diminished, some mobility and power of movement also are regained; thus restoring mastication, deglutition and speech so far, that the person at length experiences no great inconvenience from the displacement.

*Treatment.*—Reduction is readily accomplished by retracing the displacement. The Surgeon standing in front of his patient, introduces his thumbs—protected by a cloth—into the mouth, and applies them to the lower molar teeth on either side; depressing the angles of the jaw, the chin is raised by the fingers externally at the same time, and the jaw is jerked in or returns with a snap. Dislocation on one side is reduced in like manner; and so also partial dislocation, which may, however, be

returned by the natural efforts to open and shut the mouth, the patient being told at the same time—as suggested by Professor Pirrie—to bring the jaw forward. A four-tailed bandage must then be applied, as in fracture of the lower jaw; and the patient fed on liquid food for some days, during reparation of the ligaments. After partial dislocation, the prevention of its recurrence may be aided by tonic treatment, and stimulant applications over the articulation.

Reduction has been effected after periods varying from days to several weeks; after one month and five days, by Sir A. Cooper, in a case of double dislocation; and after ninety-eight days, Donovan succeeded, in another case.

*Congenital Dislocation of the Lower Jaw*—denied by Malgaigne, but affirmed by Guérin, R. W. Smith, and Hamilton; is, however, very rare. In Dr. Smith's complete account of one such case; dissection showed an arrest of development of the dislocated side of the face; the osseous and muscular structures being atrophied and imperfect. A singular deformity of the face was thus occasioned, on the one side as compared with the other; and the usual signs of dislocation were absent or reversed,—the front teeth of the upper jaw projected beyond those of the lower, the mouth was closed or opened voluntarily, and these movements of the jaw were more extensive than in the normal condition.

This congenital dislocation is incurable.

DISLOCATIONS OF THE SPINE are almost necessarily accompanied with fracture of the articular processes, and of the bodies of the vertebræ; excepting in the cervical region, the articular processes there being placed more obliquely than those of the other vertebræ. Any dislocation of the spine is rare, and more so without fracture. Separation of the *inter-vertebral substance*, and displacement of the bodies of the vertebræ, may also occur. I have seen one such case, as shown by post-mortem examination.

The *Signs* and *Symptoms* of spinal dislocation are similar to those of fracture in this region; some irregularity or projection at the seat of dislocation, and paralysis, more or less complete, of those portions of the body which receive the nervous supply from below the point at which the dislocation has occurred. The diagnosis, as compared with fracture, can hardly be determined by crepitus, which may be absent in fracture, and present in all the dislocations accompanied with fracture; but, a peculiar rigidity of the spine in the position assumed by dislocation—the trunk inclining immovably forwards, backwards, or more commonly to one side, will generally be diagnostic.

*Causes*.—The same as in fracture; falls on the head, feet, or back, and violent flexions of the spine backwards, or to either side.

*Termination*.—Dislocations of the spine are, obviously, of a serious or fatal character; and—like fracture—more so, the higher in the spinal column dislocation occurs.

*Treatment*.—Reduction of the displacement is impossible, or would be perilous; and but little can be done beyond the general treatment for fracture of the spine.

DISLOCATIONS OF THE CLAVICLE.—(1) *The sternal end of the Clavicle* may be dislocated; *forwards*, in front of the sternum; *backwards*, behind the sternum; and *upwards*, or upwards and inwards, above the sternum. In these dislocations, the ligaments are more or less completely torn, ac-

cording to the direction and extent of the displacement; but the bone carries with it the clavicular portion of the sterno-mastoid muscle.

*Signs.*—Dislocation *forwards* is denoted by a deformity, consisting of the sternal end of the clavicle in front of the sternum (Fig. 165), which disappears by drawing the shoulders backwards and returns when such force is removed; the distance between the acromion and middle line is diminished; the head is drawn forwards and turned from the dislocation, in order to relax the sterno-mastoid muscle; and there is inability to raise the upper extremity.

FIG. 165.

Dislocation *backwards* is denoted by the opposite appearance to the former one, a depression in the situation of the sternal end of the clavicle; but there may be dyspnœa, dysphagia, obstructed circulation and pain; from pressure on the trachea, œsophagus, vessels and nerves, respectively. Several cases are recorded in the "London and Edinburgh Journal of Medical Science," October, 1841. Dislocation *upwards* is of rare occurrence; four cases only having been collected by Malgaigne, and a fifth, an extraordinary case, by Hamilton, as described

by Dr. Rochester in the "Buffalo Medical Journal." This form of dislocation presents a projection above the sternum—or in the remarkable case alluded to, upon the front of the thyroid cartilage—the sternal end of the clavicle having been thrown upwards; and there is also a corresponding depression of the shoulder.

*Causes.*—A fall on the shoulder, anteriorly, or throwing the shoulder backwards, may cause the dislocation forwards; compression of the shoulders, laterally, or a direct blow on the sternal end of the clavicle, may drive this portion of the bone backwards; and a fall on the shoulder externally, or a blow upon the top of the shoulder, may start the bone upwards, upon the supra-sternal notch. In one case, this dislocation was occasioned by direct violence, a bolt thrust up from under the clavicle.

*Treatment.*—Reduction of these three dislocations is accomplished by directing the shoulder so as to retrace the particular displacement. *Forward* dislocation of the sternal end of the clavicle may thus be overcome, by drawing the shoulder backwards and outwards; in *backward* dislocation, similar traction of the shoulder, to even a greater extent, will be efficient; while *upward* dislocation may be reduced by outward traction of the shoulder, at the same time raising the outer and depressing the inner end of the clavicle. Pressure directly on the displaced end of bone, when accessible, as in the first and last named dislocations, has comparatively little effect in aiding reduction. Traction of the shoulder is best effected by using the knee as a fulcrum in the back, while an assistant places his fist as a fulcrum in the axilla; the shoulders are then bent backwards, and the elbow brought down to the side, simultaneously.

To retain the bone in position; a pad over the sternal end may have some effect in dislocation *forwards*; but a figure-of-8 bandage applied to the shoulders will more effectually prevent the recurrence of displace-

ment in *either* of the *three* directions of dislocation, the arm being drawn back and fixed to the side. Some permanent displacement and deformity are almost inevitable; the patient, however, recovering a good use of the arm.

*Compound* dislocation occurred in one instance of dislocation backwards, by direct violence. (Hamilton.)

(2) *The scapular ends of the Clavicle* may be dislocated; *upwards*, upon the upper surface of the acromion (Fig. 166); or *downwards*, under the acromion, or under the coracoid process. The first-named dislocation is the most frequent, and indeed the most common of all dislocations of the clavicle; the second very rare, only 3 cases having been recorded of dislocation under the acromion, and 6, under the coracoid process. The acromio-clavicular ligaments are torn in the dislocation upwards; and, also, the coraco-clavicular and coraco-acromial ligaments in dislocation downwards.

*Signs.*—Dislocation *upwards* is easily recognised by the projection of the outer or scapular end of the clavicle, and which is more easily felt on tracing the spine of the scapula up to the acromio-clavicular articulation. Some depression and flatness of the shoulder will also be perceptible. Dislocation *downwards* is recognised, and distinguished, by the opposite signs; a marked depression, in particular, corresponding to the usual situation of the outer end of the clavicle. Downward dislocation, under the *coracoid* process, is more particularly characterized by a corresponding projection of the acromion and coracoid process, and a rapid inclination downwards and outwards of the line of the clavicle, its outer end being felt in the axilla. Inability to raise the arm to a right angle with the body, will generally be found symptomatic of either form of dislocation; but the arm can be moved, passively, in certain directions. Thus, the range of motion is most free in the upward dislocation; whereas, in downward dislocation, under the acromion, the arm can be moved pretty freely backwards and forwards, but not outwards; and, with dislocation under the coracoid process, the arm cannot be moved inwards and upwards. Pain accompanies any opposed motion of the arm.

*Causes.*—A fall on the shoulder would seem to be the usual, or only, occasion of these dislocations; the force being applied upon the top of the clavicle, to produce dislocation downwards. Thus, in one instance, a horse trod upon the shoulder; and in another, the accident occurred to a child, from an attempt to support a great weight upon the top of the collarbone.

*Treatment.*—Reduction is easily accomplished by drawing the shoulders backwards and forwards, the Surgeon placing his knee between them, as recommended by Sir A. Cooper. Considerable difficulty will, however, be experienced in preventing the recurrence of displacement. A pad in

FIG. 166.

the axilla, and the application of a bandage, as for fractured clavicle; constitute the most effectual retentive apparatus. Direct compression is available only in dislocation upwards. Many weeks should be allowed to elapse before this treatment is discontinued. Some deformity almost always remains, but with little loss of power in the movements of the arm.

*Dislocation of Both Ends of the Clavicle* has been known to occur, simultaneously; but it must be placed among the rarities of Dislocations.

**DISLOCATION OF THE SCAPULA.**—The *lower angle* of the scapula sometimes projects, apparently having slipped from under the edge of the latissimus dorsi muscle, which there crosses the scapula. I have seen one such case, on the right side.

Any treatment is unsatisfactory, as the bone easily starts out of place again.

**DISLOCATIONS OF THE SHOULDER-JOINT.**—These are the commonest of all Dislocations. The head of the humerus may undergo dislocation; downwards, into the axilla, *subglenoid*; forwards, *subcoracoid* and *subclavicular*; backwards, on the dorsum of the scapula beneath its spine, *subspinous*. These dislocations occur in the same order of relative frequency; the first-named being by far the most common; the second, occasional; and the third, very rare. Subcoracoid dislocation has recently been regarded as the most frequent; Mr. Flower's investigations showing that of 41 specimens in the Museums of the London Hospitals, 31 are subcoracoid; and that in 50 cases known to him, 44 were of this form.

*Partial* dislocation is said to occur; either as the subcoracoid, or a dislocation upwards, under the acromion. But the former dislocation is complete, the head of the humerus being lodged entirely out of the glenoid cavity, in the illustrative case given by Sir A. Cooper; the upward dislocation is incomplete, the head of the bone lying partly in the glenoid cavity. Two such cases only are recorded, as having been verified by dissection; one by Mr. John Soden, jun., of Bath, in the "Medico-

Chirurgical Transactions," 1841; the other was taken from a subject brought to one of the dissecting rooms in Aberdeen.

**Structural Conditions.**—(1) Dislocation *downwards*, or *subglenoid*;—the head of the humerus is lodged in the axilla, just below the glenoid cavity, and resting on the inferior costa of the scapula (see Fig. 155), between the subscapular muscle and the long head of the triceps. (Fig. 167.) The

FIG. 167.

capsular ligament is torn to a considerable extent, and, generally, the tendon

of the subscapular muscle near its insertion into the small tuberosity. The muscles attached to the great tuberosity are stretched or torn, particularly the supra-spinatus; and, possibly, the tuberosity itself may be detached. The axillary vessels and plexus of nerves suffer compression by the head of the bone.

(2) Dislocation *forwards*, and *subclavicular*;—the head of the humerus lies under the pectoral muscles, on the inner side of the coracoid process, just below the clavicle (Fig. 168), and resting on the second and third ribs. The capsule may be completely separated from the neck of the bone; the lower scapular muscles much torn, namely, subscapularis detached from the smaller tuberosity, infra-spinatus and teres minor from the great tuberosity; and possibly, this prominence of bone may itself be torn away from the head of the humerus. The axillary vessels and nerves suffer compression.

FIG. 168.

(3) Dislocation *backwards*, or *subspinous*; the head of the humerus lies just behind the glenoid cavity on the dorsum of the scapula, below its spine (Fig. 169), and between the infra-spinatus and teres minor muscles. The capsule is ruptured, and the muscles in front of the joint are stretched or torn; namely, the subscapularis, supra-spinatus, and long head of the biceps.

FIG. 169.

Partial dislocation *upwards* produces structural alterations, but less extensive. In both the cases already noticed, the head of the humerus was partly dislodged upwards, under the acromion; the capsule was slightly ruptured, and the long tendon of the biceps thrown out of its groove inwards, on to the smaller tuberosity of the humerus.

*Signs.*—Certain signs are common to all three, ordinary, dislocations of the shoulder. These signs are—flattening of the shoulder, externally; a depression below the acromion, owing to the absence of the head of the bone, and a corresponding projection of the acromion above (Fig. 170) (see Fig. 156); the presence of the head of the bone in an abnormal situation, downwards, forwards, or backwards; some immobility, and inability to use the arm, and pain, particularly when the arm is moved. But, the direction of the

axis of the humerus or arm, and the length of the arm, and the situation of the head of the bone, are distinctive in each form of dislocation: thereby determining its diagnosis.

FIG. 170.

Dislocation *downwards* into the axilla, is accompanied with some inclination of the arm *outwards*, in a line with the trunk, and neither backwards nor forwards; an elongation of the arm is observable, or can be ascertained by measurement,—taking the apex of the acromion as a fixed point above the joint, and the external condyle of the humerus below. The head of the humerus can be felt in the axilla.

Dislocation *forwards* or subclavicular, is distinguished by a direction of the arm *backwards*, and somewhat outwards; with some shortening. The head of the bone can be felt under the clavicle.

Dislocation *backwards* or subspinous, is characterized by a direction of the arm *forwards*, and somewhat outwards, or occasionally, it hangs by the side; with some shortening. The head of the bone can be felt under the spine of the scapula.

*Partial* dislocation upwards—in the case recorded by Mr. Soden—was characterized, principally, by the position of the head of the bone, which appeared to be drawn higher up in the glenoid cavity, and unnaturally prominent in front; abduction produced a sensation of crepitus, the humerus rubbing under the acromion, and becoming locked as the arm was raised; and severe pain was experienced by any action of the biceps muscle.

The *Diagnosis* of shoulder-joint dislocation as compared with *fractures* of the neck of the humerus, may be determined by the presence of the signs common to all these dislocations, and the absence of true crepitus. *Atrophy* of the deltoid muscle, resulting from contusion or other injury, simulates dislocation only by the flattening of the shoulder, and the overhanging acromion.

*Causes.*—*Direct* violence, as a fall on the shoulder, in the direction opposite to the particular form of dislocation. Thus, a fall from a height on the top of the shoulder may occasion dislocation downwards; and a fall on the front of the shoulder has been known to produce dislocation backwards, or collision of the front of the shoulder against a tree, in the case of a person thrown from a horse. *Indirect* violence applied to the arm when itself in a position favourable to the particular form of dislocation. Thus, forcible abduction of the arm may occasion dislocation downwards; and I have known it produced, as a recurring dislocation in an elderly gentleman, by merely resting the fingers on a chest of drawers, the arm being fully extended. Violent contraction of the deltoid in lifting a heavy weight, has also tilted the head of the bone downwards, out of the glenoid cavity. A fall on the elbow, the arm being directed backwards, may occasion dislocation forwards; and dislocation backwards has been produced by pushing a person violently, with the arm elevated. Spasmodic contraction of the muscles during an epileptic fit, was the cause of one such dislocation, in a case examined after death by Mr. Key.

The causative relation of shoulder-joint dislocations to each other, is worthy of notice. Dislocation forwards—subclavicular—may result as the completion of a subcoracoid displacement, which is then regarded as a *partial* dislocation forwards. Or, the subclavicular dislocation may, it is said, be consequent on dislocation downwards. Sir A. Cooper regarded the former as a primary dislocation; other eminent surgeons, for example, Desault, Petit, Dupuytren, Mr. Hey, and Professor Samuel Cooper, did not deny the possibility of its being primary; but they believed it to be very seldom so, and almost always secondary to dislocation downwards.

*Unreduced* dislocation of the shoulder-joint is followed by the slow formation of a new articulation, and destruction of the glenoid cavity; with proportionate recovery of the use of the arm. Thus, in an old dislocation downwards—described by Sir A. Cooper—the head of the bone had become flattened, and a new shallow cavity had formed for the reception of the head on the inferior costa of the scapula anteriorly, a complete capsular ligament also surrounding the head (see Fig. 157); while the glenoid cavity was entirely filled with ligamentous matter, in which were suspended small portions of bone, evidently of new formation, as no portion of the scapula or humerus was broken. *Reduced* dislocation is followed by good recovery of the use of the arm; some weakness only of the shoulder-joint remaining, with increased liability to dislocation. Aggravated by its recurrence, the looseness of articulation ultimately may be such that dislocation occurs on the slightest occasion of force in the right direction. In the case already alluded to of an elderly gentleman, dislocation downwards into the axilla had been overlooked by an Hospital Surgeon in attendance for three weeks; and, after reduction by Sir William Fergusson, it occurred four times in a period of eighteen months. Upward motion of the arm was afterwards restrained by wearing a belt around the chest, attached to an arm-loop, and the dislocation has not since returned.

*Treatment.*—Reduction may be effected in various ways:—

(1) By *direct* extension and counter-extension. This method is perhaps most generally applicable. The patient being seated in a chair, a sheet or jack-towel is drawn under the axilla on the dislocated side, around the chest over the opposite shoulder, and attached to some fixed, resisting object, or held by assistants. Extension is made from the arm

or wrist, by means of a linen band fastened by a clove-hitch knot. The arm should be drawn out at a right angle to the chest, and extension slowly maintained, by an assistant, or by pulleys, when necessary. (See Fig. 160.) The Surgeon placing his knee in the axilla, and depressing the shoulder with one hand, while he slightly inclines the arm downwards with the other; the head of the bone passes into the glenoid cavity with a jerk or snap, announcing the reduction. Extension is discontinued, and the arm brought to the side should be secured by a few turns of a

FIG. 171.

roller around the chest, supporting the elbow by a few turns below. An axillary pad may be advisable in dislocation downwards. Any inflammatory swelling about the joint will subside, or can be readily subdued by cold evaporating lotions. I have thus reduced nearly all the dislocations of the shoulder which have fallen to my lot. But the inconvenience of this method in private practice, is the assistance requisite, despite the relaxing influence of chloroform, and its administration would necessitate having another assistant.

(2) By the *knee in the axilla*, reduction can be effected without extension; simply by drawing the arm well down over the knee, as a fulcrum, depressing the shoulder, at the same time, with the other hand. This was one of the methods recommended by Sir A. Cooper. (Fig. 171.)

(3) By the *heel in the axilla*. The patient lying recumbent, the

FIG. 172.

Surgeon sitting on the edge of the couch, plants his foot well up into the

axilla, and drawing the limb well downwards, inclines it inwards across the foot as a fulcrum. This also was another method employed by Sir A. Cooper. (Fig. 172.)

(4) By *raising the arm*.—The patient lying recumbent, the Surgeon sitting behind the shoulder and fixing it with one hand, raises the arm up perpendicularly; then bringing it down suddenly to the side, the head of the bone may snap into place. (Fig. 173.)

FIG. 173.

(5) Dislocation *backwards* may sometimes be readily reduced by bending the arm backwards, and, at the same time, drawing forward the upper end of the humerus, with the other hand.

*Unreduced* dislocations of the humerus are to be overcome by one or other of these methods; generally, by direct extension and counter-extension, under the influence of chloroform; aided, perhaps, by pulleys for making extension, which should be slowly maintained. Dr. Jarvis's "adjuster" has proved effectual when other means have failed. Its principal advantage is that during extension, the limb can be moved about freely in all directions, without relaxing the extension.

The *periods* after dislocation when reduction has been accomplished, vary as to their extreme duration; a month, in one of my own cases; after twenty-five weeks, by Mr. Brodhurst; after seven months, and ten months and a half, by Mr. Smith, of the United States. Dieffenbach accomplished the reduction of a dislocation forwards after two years' duration; but not until he had cut the tendons of the pectoralis major, latissimus dorsi, teres major and minor, and had divided the ligaments surrounding the new joint.

The *extreme period* for the *safe* reduction of dislocation is probably best determined by observing the movements afforded by the new joint; and which indicate also the probable *utility*, or otherwise, of reduction, although itself practicable. *Accidents*, of a most serious character, are liable to happen in the reduction of old standing dislocations; laceration of the muscles and tendons, rupture of the axillary vessels and nerves, or fracture of the neck of the humerus. These lesions may occur apart from any inconsiderate application of extending force.

*Compound* dislocation of the shoulder-joint is a rare form of injury.

Erichsen mentions having seen two cases, and in two directions, of dislocation; inwards—sub-coracoid, and—downwards—sub-glenoid; to which may be added one more, into the axilla, as recorded by Hamilton among his own cases; and a compound dislocation of the shoulder by Sir A. Cooper.

*Treatment.*—Reduction was effected in both Mr. Erichsen's cases, and they did well. The question of *amputation* must be determined by reference to the considerations which render the sacrifice of the limb inevitable in COMPOUND DISLOCATION, generally; and principally, regarding the injury to the axillary vessels and nerves.

*Dislocation, with Fracture of the Humerus, its Neck or Shaft.* (See Fig. 107.) Some such cases are recorded by Hamilton.

Their *treatment* is the only peculiarity of practical importance; as to whether the dislocation, or the fracture, should be reduced first? The former manipulation can, generally, be accomplished without much difficulty. Extension will hardly avail much, or indeed be necessary, in effecting reduction of the dislocation. Pressure on the head of the bone, aided by the relaxing influence of chloroform, has proved quite sufficient. Failing in this way; the fracture may be reduced and put up firmly, thus allowing of extension, or one of the other methods for reduction of the dislocation. Failing still to reduce the dislocation, the fracture must be alone regarded; and then at the earliest period after union of the fragments, reduction of the dislocation should again be attempted. This latter was the rule of treatment at one time, and it led to many successful results. But, it implied that which experience has since disproved, the impossibility of reducing these complicated dislocations until the fracture had united.

*Congenital Dislocations of the Shoulder-joint.*—Three varieties are recognised by Guérin; dislocation of the head of the humerus downwards; downwards and inwards, the head of the bone resting against the ribs; and subluxation upwards and outwards, the head of the bone sliding in this direction, favoured by a corresponding displacement of the coracoid and acromion processes. Dr. Robert Smith has met with only two forms of congenital dislocation of the humerus, sub-coracoid and sub-acromial; of the former he has seen several examples. These dislocations, arising from either a paralytic condition of the muscles, or from developmental imperfections of the articulation, are necessarily incurable.

DISLOCATIONS OF THE ELBOW.—This joint is liable to eight recognised dislocations; four of which relate to both bones; one to the ulna alone, and three to the radius alone. Thus (1) dislocation of both bones backwards; (2) outwards; (3) inwards; (4) forwards; (5) dislocation of the ulna alone, backwards; (6) dislocation of the radius alone, backwards; (7) forwards; (8) outwards. To these recognised dislocations may be added another; dislocation of both bones outwards, and upwards *laterally* on the humerus, constituting an "external latero-angular dislocation" of the elbow-joint, as I so named this form of dislocation, in the only instance I have ever seen or can find recorded. (See Fig. 161.)

*Structural Conditions.*—(1) Dislocation of the *radius and ulna backwards*, is the most frequent form. The head of the radius is lodged behind the external condyle, and the coronoid process of the ulna lies in the olecranon fossa; the lower end of the humerus resting on the anterior surface of the radius and ulna (Fig. 174). All the four ligaments are ruptured, leaving only some of the fibres of the internal lateral one. The

annular ligament remains entire. The brachialis anticus and biceps muscles are stretched or torn, the former sometimes carrying away a portion of the coronoid process; but the other muscles are relaxed, the triceps posteriorly, and all the muscles originating from either condyle of

FIG. 174.

the humerus, excepting the supinator radii brevis. The median nerve is pressed forwards by the humerus; and the ulnar nerve is, sometimes, painfully stretched over the projecting extremity of the ulna backwards.

(2) Dislocation of the *radius and ulna outwards*, or to the radial side (Fig. 175), is far less frequent than the foregoing, and usually incomplete; complete dislocation having been known to occur in only 11 cases. *Incomplete* dislocation; the ulna still articulates with the humerus, but the great sigmoid cavity is carried outwards from the trochlea, so that its central crest rests upon the depression which separates the condyle from the trochlea. If the annular ligament remains unbroken, the radius is displaced in the same direction and to the same extent, its head resting against and directly below the outer condyle. More complete dislocation may occur, and complete dislocation, rarely; the head of the radius being perhaps, thrown forwards or backwards.

FIG. 175.

A *variety* of this dislocation, is outwards and upwards or backwards; the olecranon process of the ulna lying above and behind the outer condyle.

The *NEW variety*, to which I have alluded, is a complete dislocation of the radius and ulna outwards and upwards *laterally*; the large sigmoid cavity of the ulna embracing the outer condyle and capitellum, just behind its articular surface, at a right angle, externally, with the humerus; and the head of the radius above, being in close relation to the external ridge of the humerus, which (ridge) bisected its round cup-like cavity. The head of the radius, therefore, was neither wholly in front nor behind the humerus; it was not dislocated forwards or backwards.

In outward dislocations, the ligaments are more or less completely torn; but, in the ordinary forms of such dislocation, the brachialis anticus and anconæus are the only muscles much disturbed, the biceps and

triceps traversing the articulation a little more obliquely; while the principal arteries and nerves do not suffer much, if at all.

In the variety which I have described, the state of the muscles is also fully noticed with the arteries and nerves; of which the latter structures had singularly escaped injury.\*

FIG. 176.

(3) Dislocation of the *radius and ulna inwards*—or to the ulnar side—is much more rare than dislocation outwards, and always incomplete, no example of complete dislocation inwards having been recorded. The ulna is driven over the elevated inner ridge of the trochlea, and falls down on the inner condyle, or epi-trochlea, embracing it instead of the trochlea; while the head of the radius, passing inwards also, occupies the trochlea. (Fig. 176.) The head of the radius is, generally, in the same line with the ulna; but it may be found a little forwards or backwards.

A variety of this dislocation, is inwards and upwards or backwards; the coronoid process of the ulna being thrust upwards above the inner condyle, and the head of the radius occupying the olecranon fossa.

The ligaments and muscles suffer some injury, and the ulnar nerve is peculiarly liable to contusion between the olecranon and inner condyle.

(4) Dislocation of the *radius and ulna forwards*, was considered impossible without a fracture of the olecranon, this opinion having been taught by Sir A. Cooper and Vidal (de Cassis); but, Monin, Prior, Velpeau, Canton, and Denucé have each reported one example—five in number. The structural condition of this dislocation requires further elucidation. In Velpeau's case, the head of the radius rested in the coronoid fossa, and the olecranon was carried upwards and a

FIG. 177.

little outwards; whereas in Mr. Canton's case, as depicted in Hamilton's work, the olecranon rested, apparently, on its summit against the forepart of the articular surface of the humerus, and the head of the radius was free lower down in the smaller sigmoid cavity of the ulna; thus constituting a complete dislocation of both bones forwards.

(5) Dislocation of the *ulna alone, backwards*, seldom happens without some dislocation of the head of the radius; yet it is possible that the coronoid process may pass backwards into the

\* British and Foreign Med.-Chir. Review, Jan., 1866.

olecranon fossa. (Fig. 177, an old unreduced dislocation. A. Cooper.) In one recorded dissection of such dislocation, observes Professor Pirrie, the coronary, oblique, and part of the interosseous ligaments were torn: the brachialis muscle was stretched under the humerus, and the triceps much relaxed.

(6) Dislocation of the head of the *radius alone, backwards*.—This dislocation (Fig. 178), is of rare occurrence, only 28 supposed examples having been collected. One only has been verified by dissection, and this is reported by Sir A. Cooper. The head of the radius was behind the external condyle of the humerus, and rather to the outer side. The

FIG. 178.

coronary ligament was torn through at its forepart, and the oblique had given way. The capsular ligament was partially torn, and the head would have receded much more, but it was supported by the aponeurotic fascia. *Incomplete* dislocation, as occasionally happens in children, may not be attended with rupture of the annular ligament.

(7) Dislocation of the head of the *radius alone, forwards*—is relatively more common than backward dislocation. The head of the radius lies in front of the humerus, and generally somewhat outwards. (Fig. 179.) The anterior and external lateral ligaments, with the annular, are, generally, more or less torn. Sometimes, the two former are alone broken, the annular ligament also being sufficiently stretched to allow of complete dislocation; or, the anterior and annular having given way, the external lateral remains intact.

FIG. 179.

(8) Dislocation of the head of the *radius alone, outwards*—is generally a modification of, if not consequent on, forward dislocation, or, perhaps, backward dislocation. The head rests on the outer side of the external condyle.

**SIGNS.**—Certain characters are common to *all* dislocations of the elbow a resemblance which renders it convenient to take these injuries consecutively, in regard to their signs, as showing more clearly their diagnosis.

Dislocation of the radius and ulna, *backwards*, presents a projection of the elbow *posteriorly*—corresponding to the extremities of both bones, and of the olecranon in particular; with another projection, the end of the humerus in front of the elbow. (Fig. 180.) There is also some shortening of the forearm, semi-flexion, approaching to a right angle

occasionally, and semi-pronation; with loss of the motions of flexion and extension, pronation and supination, but an unnatural lateral motion can generally be produced.

FIG. 180.

Dislocation of the radius and ulna, *outwards*, is characterized by an unnatural projection *externally*—the head of the radius, with a prominent projection *internally*—the inner condyle; while dislocation of the radius and ulna *inwards*, is distinguished by the opposite characters—a projection *internally* of the olecranon, and prominence *externally* of the outer condyle.

The forearm is shortened; on its inner aspect in outward dislocation, and on its outer aspect in inward dislocation; or the whole forearm is shortened, in either of these dislocations upwards. In both, there is also semi-flexion, and semi-pronation.

FIG. 181.

Dislocation of the radius and ulna *forwards*, would seem to be characterized, by *disappearance* of the olecranon *posteriorly*, and the detection of this process and the head of the radius in front of the elbow; with shortening of the forearm upon the arm, semi-flexion to a right angle, and marked supination. If accompanied with fracture of the olecranon, there will be some mobility and crepitus.

Dislocation of the *ulna* alone, *backwards*, would probably be recognised by projection of the olecranon, the head of the radius being felt to rotate in its place; by the inclination of the *forearm* to the *ulnar side*, with partial flexion, and complete pronation. If accompanied with fracture of the coronoid process, there will be considerable mobility, the dislocation readily disappearing and recurring, with crepitus.

Dislocation of the *radius* alone, *backwards*, is characterized by a projection of the head of the bone *behind* the outer condyle, where it can

be felt to rotate; while dislocation *forwards*, is distinguished by a projection of the head of the bone in *front* of the humerus. In *both* dislocations, the forearm is shortened slightly on its outer side, and inclines to *that side*, with slight flexion, and pronation. (Fig. 181.) But the latter form of dislocation is distinguished by the position of the head of the radius, and the impossibility of flexing the forearm beyond a right angle, where the head of the bone impinging on the humerus brings this motion suddenly to a deadlock. This peculiarity was first shown me, when a student, by Mr. Morton, in a case many years since at the University College Hospital; and it was a well-marked sign in another case under my own observation and treatment at the Royal Free Hospital.

Dislocation of the head of the radius, *outwards*, may be recognised chiefly by the position of the head on the outer side of the external condyle, immediately under the skin, where it can be felt to rotate.

*Causes.*—*Indirect* violence is, probably, more commonly the cause of all these dislocations. Thus, a fall on the hand may drive both bones backwards; possibly, outwards or inwards; the ulna alone backwards; or the radius alone backwards or forwards. But the position of the forearm, with regard to pronation or supination, will also affect the direction of the dislocation. Thus, the former position facilitates dislocation of the radius forwards; and a violent effort to supinate the forearm, while it is grasped and held firmly in a state of pronation, will occasion dislocation of the radius backwards. Twisting or wrenching of the forearm, as by machinery, may also occasion dislocation of both bones outwards or inwards; and less probably of either bone, the radius, in particular, backwards or forwards. The latter dislocation of this bone has been produced in children, by lifting the child suddenly from the floor by the hand, or an attempt to sustain the child when about to fall.

*Direct* violence may also be the cause of most forms of elbow-joint dislocation. Thus, both bones may be thrown backwards, by a blow upon the back and lower part of the humerus; or on the front and upper part of the forearm; or the bones are usually thrown outwards or inwards, by a blow on the side of the arm or forearm opposite to the direction of dislocation; and, in like manner, the radius alone has been started backwards, by a blow upon the front and upper part of that bone; or forwards, by a blow upon the back of the head of the radius.

Two dislocations of the elbow, I have omitted to notice, in thus describing the etiology of these injuries. Dislocation of the radius and ulna *forwards*, is, however, too rare an accident to be included in any general statement. In Velpeau's case, the man was knocked down by a carriage, the wheel passing over his right arm. Dislocation of the head of the radius, *outwards*—the other exceptional form of injury—is a modification of, or consecutive to, dislocation of that bone, forwards or backwards.

*Unreduced* elbow-joint dislocations are, probably, no exception to the pathological law of Dislocations in general; that the bones gradually adapt themselves to the particular displacement, forming a new articulation; with more or less recovery of the use of the limb. An unreduced dislocation of both bones backwards, and of seven years' duration, is depicted in Liston's Surgery. The movements of the hand were considerably regained. The structural condition acquired in such cases remains to be shown by dissection; no opportunity, I believe, having hitherto offered for this purpose. *Reduced* dislocations of the elbow generally result in a complete recovery of the use of the joint, within a few weeks.

But in one of several exceptional cases under Hamilton's observation, a dislocation of both bones backwards was easily and promptly reduced in a lad eight years old; yet, six months afterwards, the arm had become bent to a right angle, and quite stiff at the joint. Four years later, the stiffness still continued with only slight improvement.

*Treatment.*—Reduction of all the dislocations to which the elbow-joint is liable, can be effected by the same method—bending the elbow over the knee—but those of the radius are, perhaps, better accomplished in another way.

(1) Bending the elbow over the *knee*, was the method recommended by Sir A. Cooper. The patient being seated on a low chair or stool, the Surgeon resting one foot on the seat, places his knee in the bend of the dislocated joint; grasping the forearm, he presses the knee against the inner side of the forearm to unlock the ulna from behind the humerus, and drawing or bending the forearm round the knee, the bones readily come forward over the articular end of the humerus, into position. The action of the muscles will, in fact, effect reduction, when the bones are dislodged.

Another method, which seems to be a modification of the preceding, was that recommended by Boyer. Extension is made from the wrist by one assistant, the forearm remaining at a right angle with the arm, while counter-extension is made by another assistant holding the arm; the Surgeon grasping the elbow with both *hands*, presses the olecranon process downwards and forwards. This method does not so readily unlock the bones, and extension from the wrist tells more upon the radius than the ulna, which chiefly opposes reduction. It is, therefore, preferable to grasp the middle of the forearm with both hands, and draw it *forwards*; no assistant being required except, perhaps, to steady the arm.

(2) Dislocations of the radius alone, may be reduced by straight extension gradually from the wrist, the arm being fixed; aided by pressure on the head of the bone forwards or backwards, according to the dislocation. In backward dislocation also, forcible supination will aid in just throwing the head of the bone forwards over the articular surface of the humerus; while, in forward dislocation, forcible pronation will similarly jerk the head into place. But these movements are useless until the head lies on the brink of reduction, and unless while extension is still being continued.

After reduction has been effected, it should be maintained by the application of a right-angled splint upon the back of the arm and forearm, with a compress over the head of the bone—in the case of radial dislocations; and the forearm supported in a sling. The period for removal of this retentive apparatus should be regulated by the liability to re-dislocation, and to stiffness of the joint.

Dislocation with *fracture*, as of the coronoid or olecranon process of the ulna, may be treated in the same way; but retention of the bone in position must be continued for some weeks.

*Unreduced Dislocations of the Elbow*, are curable or incurable; partly according to their duration, principally however with reference to the form of dislocation. Recent dislocation of the ulna or involving the ulna, is much more difficult of reduction, than that of the radius after a long period; the difference being due to the irregular form of the head of the ulna which opposes reduction. Dislocation of the radius alone has been reduced at *periods* varying from a few days to weeks or months. In one

instance I reduced a dislocation backwards, of ten weeks' duration, and the patient, a laundress, recovered good use of her forearm. Dislocation of the radius forwards, has remained unreduced in the hands of skilful Surgeons. Sir A. Cooper failed in two recent cases; and of the six which came under his immediate observation, only two were ever reduced. Malgaigne states that in a collection of 25 cases, efforts at reduction were ineffectual in 11, and the accident was unrecognised or neglected in 6; leaving only 8, of the whole number, reduced. The golden rule should be observed in elbow-joint dislocations, as in all other such injuries, not to interfere when the motions of the joint are tolerably efficient.

*Compound Dislocations of the Elbow.*—These injuries are always perilous; both on account of their nature, the size of the joint, and as being caused by considerable violence. (Fig. 182.) The “external-latero angular” dislocation, which I have described, was compound, and produced by a wrench of the forearm between the buffers of two railway carriages.

FIG. 182.

*Treatment.*—These compound injuries present nothing peculiar in relation to their treatment. The preservation of the limb, or operative interference, by excision or amputation, must be guided by similar considerations to those which relate to shoulder-joint dislocations, or to such injuries in general.

*Congenital* dislocations of the elbow have been met with, in the form of both bones backwards, or as pertaining to the head of the radius. These imperfections are more curious pathologically, than interesting surgically.

**DISLOCATIONS OF THE INFERIOR RADIO-ULNAR ARTICULATION.**—The head of the radius in its relation to the smaller sigmoid cavity of the ulna, constituting the *superior* radio-ulnar articulation, may undergo dislocation in the directions already described, as dislocations of the head of the radius,—backwards, forwards, or outwards.

The *lower end* or head of the ulna in its articulation with the lower end of the radius, is liable to dislocation, backwards or forwards.

(1) Dislocation *backwards*, is characterized by an unnatural prominence of bone—the head of the ulna, at the posterior and inner part of the wrist, with loss of the motions of pronation and supination. In connexion with *fracture* of the lower end of the radius, this dislocation is not very uncommon; alone, it seldom occurs, 11 or 12 cases only having been collected by Malgaigne.

The *cause* would seem to be violent pronation. Thus, Desault records the case of a laundress who in wringing a wet sheet, produced dislocation of the head of the ulna backwards.

*Treatment.*—Reduction can be readily effected by forcible supination of the forearm, with pressure on the head of the ulna forwards. Generally the bone remains in place without further assistance; or it may be necessary to apply a compress and splint.

(2) Dislocation *forwards* is denoted by a projection of the head of the ulna at the anterior and inner part of the wrist; the natural prominence of this portion of the bone at the back of the wrist having disappeared. The motions of pronation and supination are lost. This dislocation is even more rare than the former; 9 cases only having been collected by Malgaigne, to which Hamilton adds 1 more, as reported by Parker, of Liverpool.

The *cause* is apparently, with hardly any exception, violent supination of the forearm. And this mode of production throws light on the comparatively less frequent occurrence of this dislocation; the motion of supination being less extensive than that of pronation, and less likely to be excessive in any of the offices which the hand has to perform.

*Treatment.*—Reduction is easily effected by forcible pronation of the forearm, with pressure on the head of the ulna backwards.

Redislocation need not be apprehended. There was no such tendency in Mr. Parker's case.

DISLOCATIONS OF THE RADIOCARPAL ARTICULATION, OR WRIST-JOINT.—This articulation may undergo dislocation backwards, or forwards.

(1) Dislocation of the hand and carpus, *backwards*, presents a large projection, the carpus at the back of the wrist, and another, the lower

FIG. 183.

end of the radius and ulna on the palmar aspect (Fig. 183 and Fig.

FIG. 184.

184); with flexure and immobility of the hand. (2) Dislocation of the hand and carpus, *forwards*, presents just the opposite appearances; a projection of the carpus in front of the wrist, and of the radius and ulna on the dorsal aspect (Fig. 185), with extension and immobility of the hand.

*Causes.*—A fall on the hand is the usual occasion of dislocation;

the back of the hand, probably, receiving the force of the shock in backward dislocation of the carpus; and the palm of the hand receiving the force in forward dislocation. These dislocations are usually said to arise conversely; but the cases described in Hamilton's work appear to clearly disprove the accepted representations in most surgical works.

*Treatment.*—Reduction can generally be effected in either form of dislocation by extension and counter-extension; position should then be maintained by antero-posterior splints securing the hand.

Fig. 185.

#### INJURIES OF THE WRIST ALLIED

to DISLOCATION.—(1) *Dislocation, with fracture* of the lower end of the radius, happens far more commonly than dislocation alone. The diagnosis will turn on the presence of crepitus and mobility of the lower fragment, as determined by moving the hand, at the same time feeling whether the styloid processes of the radius and ulna move with it. Dislocation with fracture of the posterior margin of the articulating surface of the radius, is known as "Barton's fracture." Some difficulty may be experienced in keeping the bones in place.

(2) *Fracture* of the lower end of the radius may be mistaken for dislocation of the wrist; but it can be distinguished in like manner. The comparative frequency of the former injury and rarity of the latter, led Dupuytren to almost deny the possibility of radio-carpal dislocation; though the occurrence of this dislocation is now established beyond a doubt.

(3) *Fracture with impaction* of the fragments is unattended with the usual fracture signs, mobility and crepitus; but it may be distinguished from dislocation, chiefly, by the resistance offered to reduction.

(4) *Sprain*, also, simulates dislocation: here, however, the swelling is single, and not well defined, like the bony projections of dislocation; it does not appear immediately, and gradually increases.

*Compound Dislocation of the Wrist.* This accident is of rare occurrence. One case only has been seen by Hamilton, and one recorded by Sir A. Cooper. As associated with fracture, the injury may happen more frequently. Always a serious injury, compound dislocation is even more so in consideration of the violence which causes it.

*Treatment.*—The amount of damage done to the soft textures and to the bones, will guide the Surgeon respecting the probability of preserving the hand, or the necessity for *excision* or *amputation*.

*Congenital* dislocations of the wrist, are described by Guérin as, possibly, occurring in three forms; forwards, backwards and upwards, backwards and outwards. These dislocations are connected with, and dependent on, imperfect conditions of the radio-carpal articulation, or incomplete paralysis of the muscles of the forearm and hand.

DISLOCATIONS OF THE CARPAL BONES, AMONG THEMSELVES.—Simple dislocations or rather subluxations of the carpal bones take place, it is said, occasionally; but, perhaps, only in one direction—backwards.

The bones thus liable to dislocation are; the semilunar, cuneiform, and pisiform bones of the first row, and the os magnum of the second row, which is most frequently displaced. Dislocation of any of the carpal bones may occur, in connexion with gunshot injury, or other occasions of extensive fracture of the neighbouring bones.

The *Signs* will be; a bony projection at the back of the wrist, with some loss of power.

The *Cause* is usually a fall on the back of the hand, which being thus forcibly doubled under itself, occasions one of the carpal bones to start backwards; the os magnum, for example.

*Treatment*.—Pressure may easily replace the bone, but the application of a compress, and for some time, will be necessary, to guard against redislocation; the os magnum, in particular, having a great tendency to slip out again.

DISLOCATIONS OF THE METACARPAL BONES *at their Carpal articulations*.—Any such dislocation is rare, and usually limited to a single metacarpal bone, *backwards*. The *thumb* is most commonly dislocated, and either *backwards* or *forwards* on the trapezium; the former displacement occurring more frequently.

The *Signs*, in any case, are sufficiently obvious; projection of the end, or *base*, of the metacarpal bone, in the direction of displacement, and immobility.

*Causes*.—A fall on the thumb bending it on itself, represents the ordinary mode of its dislocation. A blow upon the extremity and palmar aspect of the last phalanx may, however, cause dislocation; the force then acting in the opposite direction, or from within outwards.

*Treatment*.—Extension, with pressure on the end of the bone, will generally succeed in effecting reduction. A splint should then be ap-

plied, and perhaps a compress to prevent any risk of redislocation. The bulky base of the metacarpal bone of the *thumb* sometimes obstinately resists reduction; in which case, Sir A. Cooper recommends that the dislocation should be left to acquire the compensatory motion of a new joint,

rather than the Surgeon run any risk of injuring the nerves and blood-vessels, by dividing the muscles or ligaments.

FIG. 186.

FIG. 187.

DISLOCATIONS OF THE FIRST PHALANGEAL BONES —*at the Metacarpo-Phalangeal articulations*.—These dislocations, also, seldom happen; and usually, the bone is driven *backwards* (Fig. 186), though sometimes *forwards*. (Fig. 187.) I have seen the phalangeal bones

of the index and middle fingers partly driven back, in the left hand of a prizefighter. The first phalangeal bone of the *thumb* is most frequently dislocated, and either *backwards*, or *forwards*; the former displacement occurring more commonly. Hamilton has met with the backward dislocation seven times, the forward only twice.

The *Signs* are characteristic; a projection of the posterior extremity of the phalangeal bone, in the direction of displacement, and immobility. The *thumb* presents somewhat peculiar appearances. Its first phalangeal bone, having slid backwards upon the metacarpal bone, stands off from this bone at an angle; thus allowing the *head* of the metacarpal bone to project prominently towards the palm of the hand; while the second or ungual phalangeal bone is flexed upon the first, and forms another angle in the thumb. The phalangeal bone is locked in its new position, and reduction may be proportionately difficult. This immediately arises either from the constriction of the neck of the bone between the lateral ligaments, as Hey believed; or between the two heads of the short flexor, as affirmed by Malgaigne, Vidal (de Cassis) and others; or from the interposition of the anterior ligament torn from its attachments and folded in between the joint, as alleged by Pailloux and many others. Displacement of the long flexor tendon inwards or outwards, so as to impede reduction, has been found by Lisfranc, Deville, and Wadsworth.

*Treatment*.—Reduction can sometimes be accomplished easily; by extension, inclining the finger towards the palm, with pressure on the displaced end of bone. (Fig. 188.) Or, the thumb may require more

FIG. 188.

powerful traction; as by means of a strong tape fastened on the phalanx with a clove-hitch knot (Fig. 189), care being taken to protect the skin by a piece of moist wash-leather wrapped round the part. Or pulleys may be had recourse to, applied in like manner. A more effectual mode of extension occasionally, is by means of a large door-key; which, I believe, Mr. Liston originally suggested. Passing the ring of the key over the thumb, and hitching it against the projecting end of bone; extension and pressure can thus be brought to bear advantageously, and simultaneously. Before applying any such extending force, reduction may be facilitated by soaking the thumb for some time in warm

FIG. 189.

water, in order to relax the parts as much as possible; a very useful recommendation given by Sir A. Cooper.

*Subcutaneous section* of the opposing ligaments or tendons, should be resorted to as the last resource. It was employed successfully by Mr. Liston in a recent case—not an hour having elapsed, the patient an old man and very drunk; no resistance, apparently, to reduction existed, and very powerful force had been applied and persevered in without avail. At last, the external lateral ligament was divided by the point of a very narrow and fine bistoury; and then replacement became immediate and easy. Some inflammation followed, but was kept within bounds, and the man regained the use of the articulation.

DISLOCATIONS OF THE MIDDLE, AND UNGUAL, PHALANGEAL BONES, occur even less frequently than dislocations of the first row. Their pathology, signs, and treatment, are similar.

*Compound Dislocations of the Bones of the Hand.*—Those of the *thumb* are most common, as they are also the most serious and important with regard to the future use of the hand. But any such dislocation is usually connected with fracture, and extensive laceration of the palm.

The *causes* of these injuries are always some occasion of extreme violence. The explosion of a flask of powder in the hand happens now and then, driving one or more of the bones backward, and otherwise shattering the hand. I have had to deal with two such accidents.

*Treatment.*—*Reduction* can usually, be effected without difficulty; the obstacles of ligaments or tendons having already given way as part of the injury. The wound should then be closed, and the joint fixed, as in ordinary compound dislocations. Generally, however, the extent of injury requires some operative interference. *Excision* of splintered portions of bone, or *amputation* of one or more fingers, may therefore become unavoidable alternatives. The preservation of the thumb, and perhaps of the little finger with it, is always a consideration of paramount importance. This remnant hand will serve the useful purpose of a hook, or of prehension by the conjunction of the thumb and finger.

*Congenital Dislocations of the Fingers.*—The last three fingers of the left hand in a fœtus examined by Chaussier, were found to be dislocated at the metacarpo-phalangeal articulation. The thighs, knees, and feet were also dislocated. The last two phalanges of the fingers are, M. Bérard states, incurved backwards, occasionally, in newly-born children of the female sex; and Malgaigne has himself seen a woman in whom from birth, all the *phalangettes* were carried backwards to an angle of  $135^{\circ}$ , leaving the heads of the phalanges projecting forward under the skin.

DISLOCATIONS OF THE PELVIS.—(1) The *Symphysis-pubis*, and the *Sacro-iliac Articulations*; may, severally, undergo separation and displacement. In one case, I found all three articulations completely separated, in a young man whose pelvis had been subjected to severe compression.

The *Signs* of any pelvic disarticulation are sufficiently obvious; some deformity and mobility at the seat of injury.

The *cause* of disarticulation is always some extreme violence, and generally a compressing force.

*Treatment.*—The same as in fracture of the pelvis.

(2) The *Coccyx* is more frequently bent or displaced than fractured. Such dislocation may be *forwards*, as the result of a fall; or *backwards*, in consequence of pressure by the head of the child during parturition.

*Treatment.*—The same as for fracture of the coccyx.

DISLOCATIONS OF THE HIP-JOINT.—This joint is subject to four principal dislocations; and to five anomalous dislocations; resulting from the freedom of motion of the hip—as a ball-and-socket joint—in all directions. The number of *possible* dislocations may therefore be added to by increasing experience; any point in the circumference of a circle representing a direction in which dislocation of the hip might possibly occur, from the joint as a centre. Taking the four principal dislocations of the hip, in their order of frequency, they are as follow :—

(1) Dislocation, upwards and backwards on the *dorsum ilii*; (2) upwards and backwards into the great *ischiatric notch*; (3) downwards and forwards into the *obturator foramen*; and, (4) upwards and forwards upon the *pubes*. To these may be added, as anomalous and occasional dislocations; (5) Dislocation, *directly upwards*, between the anterior superior and inferior spinous processes of the ilium, or thereabouts; (6) *downwards* and *backwards*, upon the posterior part of the body of the ischium, between its tuberosity and its spine; (7) downwards and backwards, into the lesser or *lower ischiatic notch*; (8) directly downwards, beneath the lower border of the *acetabulum*; (9) and, forwards, into the *perineum*. The first four-named dislocations severally require special consideration; but even their relative frequency is very different. Sir A. Cooper states that in 20 cases of hip-joint dislocation; 12 will be on the *dorsum ilii*, 5 into the *sciatic notch*, 2 into the *thyroid foramen*, and 1 upon the *pubic bone*.

DISLOCATION UPWARDS AND BACKWARDS; (1) ON THE DORSUM ILII, AND (2) INTO THE GREAT ISCHIATIC NOTCH.—*Structural conditions.*—(1) The head of the femur rests on the *Dorsum Ilii*, or within the fibres of the deeper gluteal muscles; and it is directed backwards, the great trochanter forwards. (Fig. 190.) The capsular ligament, and especially its posterior half, is lacerated, and the round ligament ruptured; the small external rotator muscles are stretched or rent completely asunder, and the *gluteus maximus*, *medius*, and *minimus* torn up more or less in extent from the *dorsum ilii*; thus allowing the head of the femur to occupy its unnatural situation. The *triceps adductor* is put upon the stretch. The particular direction of the head backwards and trochanter forwards, has been attributed to the strong anterior portion of the capsule which proceeds to the anterior intertrochanteric line, still remaining entire; and thus resisting the action of the rotator muscles. Resistance to reduction in this, and other dislocations of the hip, has been ascribed either to the rent capsular ligament entangling the head and neck of the bone; or to opposing muscles; or to both this ligament and the muscles.

FIG. 190.

(2) Dislocation into the great *Ischiatic Notch*, corresponds so nearly

in its pathology, with that on the dorsum ilii, as to require only a *differe*ntial description. The head of the femur lies in the great sciatic notch, behind and a little above, the acetabulum; being situated between the upper margin of the notch above, and the sacro-sciatic ligaments below. (Fig. 191.) It rests upon the pyriformis muscle; or upon the gemelli and sacro-sciatic nerve, as in a case dissected by Mr. Syme. The attitude of the bone, and rupture of the ligaments and muscles, are very similar to the condition of dorsal dislocation.

FIG. 191.

FIG. 192.

*Signs.*—(1) Dislocation on the *dorsum ilii* presents very characteristic appearances. The limb is shortened to an extent varying from one inch and a half as the average, to three inches occasionally; the knee is slightly flexed, and the thigh upon the abdomen, thus projecting the knee forwards; there is marked inversion of the limb, the knee being directed inwards, as well as forwards, towards the other, and just above it, the foot also is inverted, so that the great toe rests on the opposite ankle. (Fig. 192.) The head of the femur in its new situation, with the gluteal muscles, give an unnatural prominence to the posterior aspect of the buttock, and the bone can be felt, especially on rotating the limb; the prominence of the great trochanter is diminished, and drawn upwards and turned forwards near the anterior superior spinous process of the ilium. Immobility of the limb, at least in the direction of eversion, abduction, and extension, will be more or less complete; and the patient has lost the power of such voluntary motion; great pain also attends almost any movement of the limb. (2) Dislocation into the great *sciatic notch*, presents similar signs, but in a lesser degree; thus rendering the characteristic appearances less marked. Shortening has taken place to an extent usually of half an inch, and not exceeding an inch. Flexion and inversion

are such, that the axis of the dislocated thigh points the knee more across the opposite thigh, and the end of the great toe rests on the ball of the great toe opposite. (Fig. 193.) The hip appearances are less conspicuous; the head of the femur sinking into the hollow of the notch, and the great trochanter approaching less nearly to the anterior superior spinous process of the ilium.

FIG. 193.

The *diagnosis* of these dislocations from other injuries is, generally, clear. *Fracture* of the neck of the femur accompanied with *inversion* of the limb, is comparatively rare; and when it occurs, mobility and crepitus of the fragments will, usually, determine the diagnosis. *Impacted fracture*, however, with consequently an absence of these signs, is always an equivocal condition. Two points of distinction between dislocation of the hip upwards and backwards, and impacted fracture, are laid down by Erichsen; that in dislocation, the head of the bone can be felt in its new situation by deep manipulation of the gluteal region; and that the trochanter is diagonal in its relative position to the anterior superior spinous process, but, in fracture, it lies nearly in a perpendicular line with it. *Disease* of the hip-joint resembles dislocation upwards and backwards, in its general characters; and particularly when advanced to the stage of shortening of the limb. The antecedent history of limping lameness and pain, before any such resemblance becomes established will sufficiently decide the diagnosis. Failing to recognise the nature of the case, instances have occurred of attempted reduction in hip-joint disease; a sad mistake, and which would sorely aggravate the disease.

**CAUSES.**—The attitude of the limb at the time of dislocation is always most influential in this, as in other such injuries. When the body is bent forward on the thigh or the thigh on the abdomen, and the thigh in a state of adduction close to the opposite thigh; hip-dislocation upwards and backwards may, then, result from a fall on the foot or knee, and especially while the individual is carrying a load on the back; or from the fall of a heavy weight, as a mass of earth, upon the back of the pelvis, the body being much bent forwards. Dislocation may thus take place either on the dorsum ilii, or into the great sciatic notch; but, to gain the latter situation, the limb must be in a position more nearly at a right angle with the trunk.

*Unreduced* dislocation of the hip backwards proceeds to the formation of a new joint; the pathology of which may be regarded as the type of any such compensatory construction, and is, therefore, considered in the general history of **DISLOCATION**.

Cases are on record showing the efficiency of the limb eventually, in a

state of unreduced dislocation; one—related by Hamilton—after nine years dislocation on the dorsum, where a young man could walk rapidly, although with a halt, yet without pain and discomfort; in another case, after only eight weeks' dislocation into the sciatic notch, the limb was quite useful. Reduction of dislocation on the dorsum, is, generally, followed by speedy recovery of the use of the limb; in the course of a few weeks or months at most, the limb becoming as sound and useful as before. The same may be said in favour of dislocation into the sciatic notch; reduction soon restores the thorough efficiency of the limb.

TREATMENT.—Chloroform should always be administered — unless specially contra-indicated—to relax the muscles. A warm bath may be substituted for the relaxing influence of chloroform, in exceptional cases. *Reduction* can then be effected in either of two ways; by extension and counter-extension of the limb, pulleys being necessary to overcome the muscular resistance and its duration, in most cases; or by flexing the limb on the thigh, and guiding it so into position, that the muscles themselves, probably, complete the reduction—constituting the method by “manipulation.”

(1) *Extension and Counter-extension.*—The patient must be placed on his back, inclining to the side opposite to that of dislocation; and sufficiently raised from the ground on a bed or table, that the long axis of the thigh may be in a line with the force of extension, resisted by counter-extension, which should be applied in the following manner. (Fig. 194.) A padded belt is fastened round the lower part of the thigh, having a double strap attached to it, terminating in a ring; to the latter a multiplying pair of *pulleys*, of three cords, is hooked, whereby extension is brought into operation; the distal pulley being hooked to a ring or *staple* driven into the wall or some firmly fixed object, in a line with the thigh. A padded *perineal band*, for counter-extension, must be secured in like

FIG. 194.

manner. An apparatus of this kind, and well adapted for the purpose, is manufactured by Messrs. Weiss. The cord of the pulleys may be entrusted to an assistant, the Surgeon taking charge of the thigh and hip. Extension should be made *slowly*, gradually increased, and steadily maintained. The great trochanter will be observed to descend and to come more into position, as extension proceeds; the upper part of the thigh should then be raised with one hand or by means of a towel passed under the thigh, in order to lift the head of the femur over the prominent brim of the acetabulum; while at the same time rotating the thigh outwards, with the other hand, thus to incline the head of the bone downwards and

forwards; it will, generally, be felt to slip in with a jerk, rather than a snap, the muscles being worn out beyond the power of any sudden contraction. On relaxing the extension, the perceptible disappearance of the signs of dislocation, in the length of the limb, &c., announces the certainty of reduction. The limb must then be retained in position, to guard against the liability of re-dislocation. A long splint and bandage, as for fracture of the thigh, has been recommended for this purpose; but simply connecting the reduced limb with the sound limb, by means of a few turns of a bandage around the thighs side by side, I have always found to afford a sufficient security. The patient must remain in bed for ten days or a fortnight, during the reparation of the ligamentous and other tissues.

Dislocation into the *sciatic notch* is accomplished in like manner, but with greater difficulty, owing to the imbedded position of the head of the femur. (Fig. 195.) Extension should be made across the middle of the opposite thigh, and the head of the bone more lifted out of its bed; the patient inclining more to the opposite or sound side. To effectually raise

FIG. 195.

the head of the bone, it is sometimes recommended, that a towel passed under the thigh, should be looped round the neck of an assistant, who stooping over the pelvis and pressing downwards with both hands, raises his shoulders; thus bringing considerable power to bear in drawing the bone forwards towards its socket.

*Manual* extension may succeed, especially if aided by the influence of chloroform, in effecting reduction of hip-joint dislocation. This alternative extending force is, therefore, a valuable resource in the absence of pulleys, which cannot always be at hand. I thus succeeded in reducing a dislocation of the hip, on the *dorsum ilii*, and of twenty-four hours' duration, where also the belt and straps, which were new and sound, had given way in using them.

(2) *Manipulation*.—This method of reduction was known to Hippocrates, and has since been variously practised by Surgeons in modern times; but, in 1851, Dr. W. W. Reid of Rochester, N. Y., so attracted the attention of the profession to this proceeding, as to have fairly introduced it as an established method of practice.

Dr. Reid's method consists:—"In flexing the leg upon the thigh, carrying the thigh over the sound one, upwards over the pelvis as high as the umbilicus, and then abducting and rotating it outwards."

Hamilton's description of the proceeding is this:—"The patient being laid on his back upon a mattress, the Surgeon—assuming that it is a dislocation on the *dorsum ilii*—should seize the foot with one hand and the

other he should place under the knee; then, flexing the leg upon the thigh, the knee is to be carefully lifted toward the face of the patient until it meets with some resistance; it must then be moved outwards and slightly rotated in the same direction until resistance is again encountered, when it must be gradually brought downwards again to the bed. We do not know that the whole process could be expressed in simpler or more intelligible terms, than to say, that the limb should follow constantly its own inclination."

In attempting the reduction of dislocation into the *sciatic notch*, by manipulation, the same author warns us of the special danger, "that the head of the bone will be thrown across into the foramen thyroideum."

"The following summary of a paper—prepared by Dr. Hamilton—with the view of determining, if possible, the relative value of the two methods—manipulation and extension—and exhibiting an analysis of 64 cases in which manipulation was employed, will enable the reader to form some estimate of the difficulty in which this subject is involved; and if it does not actually decide a moot-point, it will at least demonstrate that the method by manipulation is not without its hazards. Of 41 cases in which the fact is stated, 28 were reduced on the first attempt, 7 on the second, 4 on the third, and 2 on the seventh. In 7 examples, the head of the femur has been thrown from one position to another upon the pelvis, travelling from the dorsum ilii to the ischiatic notch, and from thence to the foramen ovale; or directly from the dorsum to the foramen, and back again; or in other directions, according to the character of the original dislocation; in some instances these changes being made as often as seven times in succession. In the majority of cases, no evil consequences seem to have followed upon these changes of position."

FIG. 196.

DISLOCATION DOWNWARDS AND FORWARDS INTO THE OBTURATOR FORAMEN.—*Structural Condition.*—The head of the femur lies in front of the obturator foramen, lodged upon the obturator externus muscle, the ball being directed inwards and the great trochanter outwards. (Fig. 196.) The capsule has given way, especially on its inner side, and the round ligament is torn from its attachment; but the constancy of the latter lesion is disputed.

*Signs.*—This dislocation, also, presents very characteristic appearances. The limb is lengthened from one to two inches in extent, the knee bent, and the body inclined forwards—apparently to relax the painful tension of the psoas and iliacus muscles; and the whole limb is in advance of the other, and much abducted, the foot usually points forwards, but occasionally it is slightly everted. (Fig. 197.) The head of the femur can be felt in its new situation, particularly

in thin persons; and the prominence of the great trochanter has disappeared entirely, presenting a marked flattening of the hip, or a depression in the situation of the trochanter.

*Causes.*—The limb must be in a state of abduction, at the moment of

injury. Any force from below, or acting on the back, may then produce dislocation downwards and forwards, into the obturator foramen. Thus, a fall from a horse, with the thigh under the body of the animal, has had this effect; and Pirrie once found it caused by the person jumping in great haste out of bed, and while the left foot reached the floor, the right was entangled by the blankets in bed, thus separating the legs and thence producing dislocation into the obturator foramen. The fall of a heavy weight upon the back of the pelvis when the body is bent forwards and the thighs are apart, will also produce the dislocation.

FIG. 197.

FIG. 198.

*Treatment.*—(1) The patient is laid on his back. *Extension* must be made upwards and outwards by a perineal girth connected with the pulleys; and counter-extension maintained by another belt around the pelvis from the dislocated side. As the head of the bone is thus drawn towards its socket; the Surgeon passing his hand behind the sound limb, grasps the ankle of the dislocated limb, and drawing it inwards and backwards towards the middle line, thus throws the head of the bone outwards and upwards to the acetabulum. The limb is here used as a long lever, over the resisting perineal girth, as a fulcrum. (Fig. 198.) This is Sir A. Cooper's method of reduction. Other methods have been devised, but they do not correspond more nearly to the direction of the displacement.

In the absence of pulleys, however, it is well to have other resources, as follow:—

(2) Let the patient sit upon the front of the bed, astride one of the bed-posts, and grasp it; while extension of the limb is made by two

assistants. Then, the Surgeon crossing the limb over the sound one, and rotating it outwards, may thus succeed in reducing the dislocation. This method was proposed and practised with success by Mr. Hey, of Leeds, in one case.

(3) Manipulation seems to have succeeded in another case. Mr. Hey flexed the thigh to such an extent as to form an acute angle with the trunk, and then by rotating it, accomplished reduction.

DISLOCATION UPWARDS AND FORWARDS UPON THE PUBES.—*Structural Condition.*—The head of the femur rests on the anterior margin of the horizontal ramus of the pubic bone, with the great trochanter directed backwards. (Fig. 199.) Sometimes, the ball is driven up so high as to be hooked into the pelvis. The capsular and round ligaments are ruptured. In a case, dissected by Sir A. Cooper, Poupart's ligament was torn, so as to allow the head and neck of the bone to pass underneath the iliacus internus and psoas muscles; the anterior crural nerve lying upon these muscles and stretched over the neck. The femoral vessels were to the inner side.

FIG. 199.

FIG. 200.

*Signs.*—The limb is shortened, generally to the extent of an inch; flexed slightly, decidedly abducted, and everted. (Fig. 200.) The globular head of the femur can be plainly felt on the pubic bone, to the outside of the femoral vessels, and made to roll under the fingers by rotating the limb; while the prominence of the great trochanter has disappeared, this portion of the bone being drawn inwards and upwards towards the anterior superior spinous process of the ilium. Immobility of the limb is a marked symptom, as regards rotation inwards; and powerlessness equally so, with pain or numbness frequently, owing to pressure on the anterior crural nerve.

The *diagnosis* from *fracture of the neck* of the femur, may be determined; by the situation of the head of the bone and immobility, with crepitus in the case of fracture; or if the fracture be *impacted*, the head of the bone is still diagnostic.

*Causes.*—When the limb is directed backwards, and perhaps, abducted; dislocation upon the pubes may occur. Either, by a fall on the foot, as when a person slides down from the end of a waggon; or when walking, the foot is suddenly planted into a hole, the pelvis advances, while the upper part of the body is thrown forcibly backwards, in order to avoid a fall. A severe blow on the back of the pelvis may have the same effect in producing dislocation upon the pubic bone.

*Unreduced* dislocation leads to the formation of a tolerably complete new joint. This result was found in the case examined by Sir A. Cooper. Upon the pubes a socket was formed for the neck of the femur, the head being above the level of the pubes. Both the latter portions of bone were flattened; the trochanter also was much altered in shape, and it partly occupied the acetabulum, which was otherwise filled with osseous deposit. This specimen is still in the Museum of St. Thomas's Hospital.

*Treatment.*—The patient lying on his back, with the dislocated side near the edge of the bed; Extension should be made from the lower part of the thigh, downwards and backwards, the pulleys being fixed accordingly; while counter-extension, by means of a perineal girth, is made in the opposite direction, over the body of the patient. (Fig. 201.) This

FIG. 201.

force having, as usual, been applied slowly, gradually increased, and steadily maintained; the head of the bone is lifted over the brim of the acetabulum, by a towel under the upper part of the thigh, and the ball directed backwards, by rotating the thigh inwards.

"Anomalous" Dislocations of the Hip, in the various modified directions already enumerated, occur too rarely to admit of any precise description. The *signs* resemble in various degrees, those of the principal dislocations; and the *treatment*—by extension and counter-extension—must be modified according to the particular direction of dislocation.

UNREDUCED DISLOCATIONS OF THE HIP.—*Two months* was the period fixed by Sir A. Cooper, as the extreme period within which such dislocations can, or should, be reduced. Increasing in difficulty and danger, as the operation of reduction may be up to that time; it subsequently becomes extremely uncertain of accomplishment, and always perilous, owing to the liability of fracture or of abscess, from the straining injury to the soft textures. The former accident has occurred in the hands of some of the most able Surgeons; fracture taking place usually in the neck

of the femur or not far below the trochanters. *Exceptional* cases of successful reduction after a much longer period have more recently been recorded. Thus, two cases are cited by Hamilton, both of *six months* standing, and it may be added, both dislocations on the dorsum ilii.

The physiological consideration which, as a *rule*, should here, as in regard to all Dislocations, guide the Surgeon, is, the *degree of efficiency* of the new joint; as indicating the practicability and safety of attempting reduction, and its utility when accomplished.

*Dislocation of the Hip, with Fracture of the Femur.*—This complication is undoubtedly possible, but exceedingly rare. Reduction of the dislocation is said by Hamilton to be still more rare. The *rule of practice*, however, should always be to attempt reduction at the time of the accident. This may be accomplished, under the influence of chloroform, simply by pressure on the head of the bone and with the requisite manipulation; or, by first setting the fracture and securing it with lateral splints, in order to make use of the limb for extension in reducing the dislocation. Failing at the time of dislocation to effect reduction, union of the fracture must be allowed to take place, and then it should be again attempted. This resource proved successful in one case, a dislocation on the dorsum ilii, of five weeks' duration; Mr. Badley being the operator. In another case, a dislocation into the sciatic notch; reduction at the end of six weeks, as reported by Mr. Thornhill, appears to have been doubtful. It would seem that, probably, he re-fractured the bone; for the head of the femur is said to have resumed its place with a loud *crash*.

*Double Dislocation*—i.e., of both hips, has been known to occur; and in different directions on the two sides, or with fracture of one femur.

*Congenital Dislocations of the Hip-joint* have been met with, complete or incomplete. The former correspond very nearly in their directions with the regular dislocations of the hip, and with one of the anomalous varieties—upward dislocation, in which the head of the femur is placed outside the anterior inferior spinous process of the ilium. These dislocations seem to occur much oftener in females than in males; and usually, they are single.

DISLOCATIONS OF THE PATELLA are liable to occur in four directions; (1)

FIG. 202.

outwards more commonly, or (2) inwards; (3) vertically, the patella turning edgewise on its axis; or lastly, (4) upwards. Both the latter forms of dislocation are very rare.

(1 and 2) Dislocation laterally, *outwards*, or *inwards*. The *structural conditions* in these two forms of Dislocation are analogous; the patella is displaced more or less completely, in either direction, and rests on the outer side of the external condyle (Fig. 202), or the inner side of the internal condyle (Fig. 203), of the femur.

FIG. 203.

*Signs.*—An unnatural swelling—the projection of the patella, can be seen and felt over the outer or inner condyle; with an unnatural depression in front of the knee, owing to the absence of the bone from its proper situation. The knee is much broader than usual, slightly bent, and immovable; considerable pain also is experienced, especially aggravated by any attempt to bend the joint.

*Causes.*—*Muscular contraction* of the quadriceps extensor would seem to be the usual cause of these dislocations. The *outward* displacement is particularly liable to occur in persons who are knock-kneed, or whose external condyles have not the usual degree of prominence anteriorly. Dislocation of the patella in this direction may sometimes be produced *voluntarily*. A dancing girl, who, from her earliest years, had habitually twisted herself into various attitudes, eventually became knock-kneed; and when the rectus muscle acted upon the patella, it was thrown nearly flat upon the side of the external condyle of the femur. Sir A. Cooper—who relates this case—also found the dislocation reproduced in another instance whenever the limb was extended, displacement arising from *distension* of the joint with *synovial fluid*. *Indirect* violence is sometimes the cause; as a sudden twist of the thigh inwards, while the weight of the body resting on the foot, keeps the leg turned outwards; or a fall with the knee turned inwards, and the foot outwards. *Direct* violence, as a blow upon the inner or outer margin of the patella, may sometimes produce dislocation outwards or inwards, respectively.

These dislocations are very prone to recur.

*Treatment.*—Reduction is easily effected. The patient lying on his back, the Surgeon raises the thigh towards the abdomen, so as to relax the quadriceps extensor muscle; and then by pressing the patella inwards, or outwards, over the condyle, it is at once drawn into place by the action of that muscle.

(3) In *vertical* dislocation, the patella turns on its axis and presents edgewise. One margin looks forwards, the other rests and is fixed, in the groove between the condyles. This twist may be more or less complete; whereby the margin of the bone looks obliquely forwards, or turns almost completely round so that the posterior surface of the bone partly becomes anterior. The latter displacement is very rare; and indeed, any vertical dislocation is uncommon, not more than fifteen examples having been recorded.

*Signs.*—Vertical dislocation presents very characteristic appearances; the sharp projecting border of the patella can be clearly felt and seen under the skin; and the leg is forcibly extended, or sometimes flexed slightly.

The same *causes* may turn the bone vertically on its axis, which displace it laterally; and—as Hamilton states—an incomplete lateral may be converted into a vertical dislocation, if the bone hitches on one margin, and the extensor muscle contracts suddenly and violently, thus raising the other margin, or even completely turning the bone on itself.

*Treatment.*—*Reduction* can sometimes be accomplished with tolerable facility, or it may be extremely difficult, and sometimes impracticable, the margin of the patella being, it would appear, mechanically fixed in the intercondyloid fossa. The same method of reduction is applicable as for lateral dislocation; relaxation of the muscles by raising the thigh, and pressure on the patella, laterally on both margins, but in opposite directions. Or, forcible flexion of the knee, with rotation of the tibia on the

femur, may succeed; forcible flexion and extension alternately, has also proved successful, or a violent effort by the patient to make these movements. This failing, *subcutaneous section* of the tendon of the quadriceps and of the ligamentum patellæ, has been resorted to. But, in a case related by Mr. B. Cooper, from "Rust's Magazine," in his edition of Sir A. Cooper's work, this proceeding was more than unsuccessful; reduction was still impossible, and extensive suppuration followed, under which the patient sank and died.

(4) Displacement *upwards* can only result from relaxation, or rupture, of the ligamentum patellæ; thus permitting the patella to glide upwards in front of the femur. I have seen this occur once, from forcible flexion of an ankylosed knee-joint.

The *Signs* of such displacement are sufficiently obvious. The patella is drawn upwards, an interval appears below it, or a fold inwards when the leg is placed in an extended position; there is also marked mobility of the leg and proportionate loss of extensor power, the leg hanging down nearly useless and swinging to and fro like a pendulum.

The *Treatment* is the same as for fractured patella, or rupture of the quadriceps tendon. In the case referred to, the power of extension was but partially recovered.

**DISLOCATIONS OF THE KNEE.**—This joint is seldom dislocated; nevertheless, the head of the tibia is liable to undergo dislocation in four principal directions, and in the following order of relative frequency: (1) inwards, (2) outwards, (3) forwards, (4) backwards. The first two dislocations are always incomplete; the latter two may be incomplete or complete. Velpeau has found on record 13 examples of complete dislocation forwards, and 8 backwards.

#### *Structural conditions.*

FIG. 204.

—(1) Dislocation of the head of the tibia laterally, *inwards* (Fig. 204); the external condyle of the tibia rests upon the internal condyle of the femur, and the lateral ligaments are more or less completely ruptured. (2) Dislocation laterally, *outwards* (Fig. 205); the internal condyle of the tibia rests upon the external condyle of the femur, and the lateral ligaments are more or less entirely ruptured.

FIG. 205.

(3) Dislocation of the head of the tibia, *forwards*; the head is situated

partially, or entirely, in front of the condyles of the femur, according as the dislocation is incomplete, or complete. The condyles of the femur project, proportionately, backwards in the popliteal space. (Fig. 206.)

(4) Dislocation of the head of the tibia, *backwards*; the head is situated partly upon the posterior half of the condyles of the femur, or it passes up and rests against the posterior aspect of their articulating sur-

faces, according as the dislocation is incomplete or complete. The condyles of the femur project, proportionately, forwards. (Fig. 207.)

FIG. 206.

FIG. 207.

In both the latter dislocations, (3) and (4), it is probable that the ligaments and surrounding structures are similarly injured. Thus, in backward dislocation, the posterior ligament of the joint is torn, the muscles of the ham are stretched, and the popliteal vessels and nerves compressed. With *complete* dislocation, the crucial or inter-articular ligaments are also torn.

*Signs.*—(1) Dislocation laterally, *inwards* or *outwards*, presents oppo-

site appearances. In the one, an unnatural swelling, the inner condyle of the tibia, on the inner aspect of the knee; and another swelling—the external condyle of the femur, on its outer aspect. In the other dislocation or outwards, an unnatural swelling, the outer condyle of the tibia and head of the fibula, is found on the outer aspect of the knee; and another swelling—the internal condyle of the femur, on its inner aspect. In both forms of dislocation, the leg is slightly flexed, or sometimes extended, and twisted, inwards or outwards, towards the side of dislocation, but *not* shortened. Immobility, with inability to use the leg and severe pain, are present, as more or less, in all dislocations. All these signs or symptoms were marked in two lateral dislocations; one of which occurred in my Hospital practice; the other, an outward dislocation, in the case of a lady, well known to me, but who, at the time of the accident, many years since, was under the able care of Mr. Pitt, of Norwich. This case is recorded in the "American Journal of Medical Sciences," vol. xxxi.; and it is also noticed in Hamilton's work. Mr. Pitt's patient quite regained the use of her leg: similar dislocation again occurred about a year afterwards, and was reduced in the act of carrying the patient up-stairs, by her foot accidentally getting entangled in the bannister-rails; it happened again about three months subsequently, when the knee jerked into place spontaneously; and I am happy to say, that excepting a slight weakness of the knee, she now suffers no inconvenience.

(2) Dislocation *forwards* or *backwards*, also presents opposite appearances. In the one, a large swelling, the bulky head of the tibia, projecting in front of the knee, with a deep depression immediately above it and the patella; and another large swelling—the condyles of the femur, in the popliteal region. In the backward dislocation, a large swelling, the bulky head of the tibia, can be felt in the popliteal space; and another large swelling—the condyles of the femur, in front of the knee, with a deep depression below in the situation of the ligamentum patellæ. In both these forms of dislocation, the leg is flexed; in the one case,

slightly back upon the thigh; in the other, extended or bent unnaturally forwards from the line of axis of the femur; shortening also is conspicuous, if either dislocation be *complete*, and varying in extent from one to two inches, or more. Severe pain, and swelling of the limb, may arise from compression of the popliteal nerves and vessels.

*Causes.*—All these dislocations of the knee usually arise in like manner. *Indirect* violence is, perhaps, the most frequent cause; as when the foot is made fast in a hole, and the tibia twisted upon the femur either by the body swinging around upon the knee; or by a fall from some height, or by the individual jumping from a carriage in motion. *Direct* violence, is represented by a blow upon the upper end of the tibia, or upon the lower end of the femur. In one remarkable case, recurring dislocation backwards was produced, as it seemed to me, by *hydrops articuli*. The head of the tibia passed backwards whenever the patient, a woman, bore any weight on her foot and attempted to walk. Similar dislocation, or a tendency thereto, is not an uncommon result of disease of the knee-joint, with retraction of the leg, causing the end of the femur to project forwards in standing or walking.

*Unreduced* dislocation of the worst form, or backwards, may terminate in the recovery of a tolerably useful limb. Three such incomplete dislocations, backwards and unreduced, have been seen by Malgaigne, and neither of the persons thus affected were very greatly maimed in consequence. One walked with crutches after three or four days, and with a cane after about five weeks. Another did not leave his bed under one month, and it was nearly one year before he could lay aside his crutches; but both of these individuals were finally able to walk at least twelve leagues a day. In a similar case seen by Lassus, the patient was confined to bed two years, yet he finally recovered a tolerable use of his limb. Reduction, promptly effected, with sufficient rest of the limb, is followed by sound recovery or very little if any maiming, ultimately. This issue may be hopefully anticipated even when dislocation has occurred repeatedly at distant intervals, as happened in Mr. Pitt's case.

*Treatment.*—Reduction can be accomplished, in the same way, in each form of dislocation of the knee. Flexing the thigh towards the abdomen, and fixing it for counter-extension, extension is then applied to the leg, in the direction of the long axis of the displaced tibia; pressure being made, at the same time, on the ends of the bones in opposite directions, so as to overcome the displacement. Thus, pressure should be applied laterally, on the head of the tibia in particular, inwards or outwards, according to these forms of dislocation; and on the same bone, downwards and backwards, in forward dislocation; or downwards and forwards, in backward dislocation. Splints should be employed to fix the joint, and the appropriate measures also for subduing inflammatory swelling which is often considerable. At the end of two, three, or four weeks, according to circumstances, passive motion may be used gently at intervals, and the joint allowed gradually to resume its functions.

*Internal Derangement of the Knee-Joint*—so named by Hey, who first described it—or subluxation of the knee, sometimes so called. This accident is not uncommon.

The *structural condition* is, probably, a partial dislodgment of one of the semilunar cartilages, owing to a disruption of its ligamentous connexion with the margin of the condyle; the thick margin of the cartilage thus becoming interposed between the articulating surfaces of the

opposed condyles of the femur and tibia; or part of the cartilage slipping before or behind the condyle, the articular surfaces are brought into contact. An analogous condition, in relation to the symptoms thence arising, may also occur; by the interposition, either of a fragment of one of the cartilages, or of an hypertrophied portion of cartilage, or of a false cartilage—a new formation, moving about more or less freely within the joint.

*Symptoms and Causes.*—Sudden inability to use the joint, is felt, which becomes locked, while walking, or by striking the toe against something, or by tripping the foot. Intense and nauseating pain accompanies this sudden locking of the joint, and the person falls to the ground. Any slight twist of the leg, as in bed, by the mere weight of the bedclothes hanging upon the toes, has been known to produce the same effect. In either case, the joint is slightly flexed, and the leg perhaps somewhat rotated. Considerable swelling of the knee rapidly supervenes, and the synovial capsule becomes distended with fluid; in short, subacute synovitis ensues from this injury.

It is very likely to recur, again and again; thus rendering the prognosis unfavourable.

*Treatment.*—This “internal derangement” disappears, in most cases, as easily as it was produced. Flexion, with sudden extension, and slight rotation of the leg, will generally overcome the difficulty, if indeed it should not suddenly right itself. Immediately, the motions of the joint become free and painless, so that the individual can walk about as if nothing had happened. But it is better to place the joint at rest for a while, subdue any synovitis which may have supervened, and then support the knee for some time by means of a knee-cap, to guard against the liability of recurrence.

*Compound Dislocation of the Knee-joint.*—This injury must be regarded as the most perilous of its kind, but fortunately it is of rare occurrence. (Fig. 208.)

*Treatment.*—An attempt to preserve the limb will scarcely ever prove successful; and, excepting in a few cases of more limited damage to the popliteal vessels, nerves, and the integuments, where excision may be sufficient, amputation is the only resource. The injunction originally given by Sir A. Cooper to sacrifice the limb, will generally be unavoidable for the probable preservation of life.

*Congenital Dislocations of the Knee.*—The head of the tibia has been found, at birth, dislocated in various directions; forwards, backwards, inwards, outwards, inwards and backwards, outwards and backwards, and simply rotated inwards. The first-named dislocation is much the most frequent; and the majority of all these congenital dislocations were incomplete. Double dislocations have been found in some instances. Thus, both tibiae were displaced backwards in an infant otherwise deformed, according to Chaussier's observations.

FIG. 208.

**DISLOCATIONS OF THE HEAD OF THE FIBULA.**—The upper end of the fibula may, occasionally, be dislocated *forwards* or *backwards*. Of the former dislocation, Malgaigne has collected three examples, unconnected with any other accident, and not apparently due to any abnormal condition of the ligaments. I have seen another, or fourth, such dislocation, which had remained unreduced. Of backward dislocation, Hamilton enumerates three cases on record.

The *Signs* of these dislocations are very palpable; the projecting head of the bone, immediately under the skin, forwards or backwards, cannot fail to be observed.

The *Cause* is almost necessarily direct violence, as a blow on the head of the fibula. But muscular action is said to have produced two, at least, of the three forward dislocations.

The consequence of any such dislocation may be a laxity of the joint, with mobility of the fibula backwards and forwards upon the tibia. This was the result in one of the backward dislocations recorded by Sanson.

*Treatment.*—Reduction having been effected by pressure, the head of the bone must be kept in place by a compress and bandage.

**DISLOCATION OF THE LOWER END OF THE FIBULA.**—The only instance of simple dislocation is related by Nélaton as having occurred in the practice of M. Gérdy. It was a *backward* dislocation, of thirty-nine days' duration, and caused by the wheel of a carriage passing obliquely across the leg so as to displace the outer malleolus, backwards. The bone was in almost direct contact with the outer margin of the tendo-Achillis, the outer face of the astragalus, abandoned by the fibula, could be plainly felt, and the position of the foot remained unaltered. The patient could walk pretty well, the bone was fixed, and reduction not attempted.

**DISLOCATIONS OF THE ANKLE-JOINT.**—The astragalus in connexion

Fig. 209.

with the foot may be dislocated from the articular ends of the tibia and fibula, in four directions; (1) outwards, (2) inwards, (3) forwards, and (4) backwards. They may be termed dislocations of the foot in these directions. Most of these displacements are accompanied with fracture of the fibula, the tibia, or of both bones. The description of these several forms of dislocation will, I think, be simplified by regarding them, conversely, as relating to the tibia.

*Structural Conditions.*—(1) Dislocation *outwards*. The lower end of the tibia is displaced laterally inwards upon the astragalus (Fig. 209); the outer portion of the articulating surface of the tibia resting upon the inner portion of the upper articulating surface of the astragalus, or it may slide com-

pletely off in the same direction. The foot is turned outwards—everted. The internal lateral ligament is ruptured, or the inner malleolus may be broken, or both; the fibula, also, usually gives way two or three inches above its articulation with the astragalus. (Fig. 210.) Sometimes, in addition to these injuries, there is an oblique fracture of the tibia upwards and outwards from the articulating surface, breaking off that portion of the tibia which corresponds to the inferior tibio-fibular articulation; this fragment remaining connected with the outer malleolus, while the tibia carries inward with it the portion of the fibula above the fracture.

FIG. 210.

FIG. 211.

(2) Dislocation *inwards*.—The lower end of the tibia, and of the fibula, are displaced laterally outwards; and, perhaps, completely, the articulating surface of the tibia entirely sliding off the upper surface of the astragalus. (Fig. 211.) The inner malleolus is broken off the tibia, but remains attached to the tarsus by the internal lateral ligament; and the external lateral ligament is ruptured, or the outer malleolus may be broken off the fibula, thus making a fracture of both malleoli. The foot is turned inwards—inverted.

(3) Dislocation *backwards*.—The lower end of the tibia is displaced forwards on the astragalus, resting partly on this bone and partly on the scaphoid bone; or completely forward, the tibia then resting on the scaphoid and internal cuneiform bones. (Fig. 212.) The foot in front of the ankle, is shortened. In the latter or complete displacement, especially, the lateral ligaments are more or less completely ruptured; generally, the fibula is fractured but on a level with the articulation; sometimes, the internal malleolus also, and still more rarely, a fracture occurs through the posterior margin of the articular surface of the tibia.

FIG. 212.

(4) Dislocation *forwards*.—This injury happens even more rarely than the preceding, but Malgaigne has collected five instances. The lower end of the tibia is displaced backwards on the astragalus, resting partly on

this bone and partly on the os calcis, behind it. (Fig. 213.) The foot in front of the ankle, is elongated. Dr. R. W. Smith believes that this dislocation is never complete, so that the tibia shall lodge entirely on the os calcis.

FIG. 213.

The lateral ligaments are ruptured, or one or both malleoli are broken.

**SIGNS.**—Dislocation laterally outwards or inwards, presents opposite appearances. *Outward* dislocation is characterized by violent eversion of the foot, its inner margin being directed downwards; the inner malleolus projects prominently under the integuments, and there is a corresponding depression above the

outer malleolus, in the situation of fracture of the fibula. Crepitus may here be detected, and the foot can be moved about pretty freely by the Surgeon, but with great pain. *Inward* dislocation is distinguished by inversion of the foot, its outer margin looking downwards; and the outer malleolus projects strongly under the skin.

Dislocation backwards and forwards, also present opposite appearances. *Backward* dislocation is attended with shortening of the foot in front of the tibia, and depression of the toes; while the heel is elongated, projecting posteriorly, and drawn upwards. The extensor tendons of the toes are sharply defined, and the tendo-Achillis is curved tensely forward. The foot is immovable. These signs are even more marked with *complete* dislocation; the end of the tibia can be distinctly felt projecting forwards, accompanied with an evident depression posteriorly in front of the tendo-Achillis. *Forward* dislocation is characterized by lengthening of the foot in front of the tibia, and elevation of the toes; with corresponding obliteration of the heel, which is in a line with the back of the leg, and depressed downwards. A portion of the articulating surface of the astragalus may be felt in front of the tibia.

**CAUSES.**—*Direct* violence; as a severe twist or wrench of the foot outwards or inwards, represents the ordinary mode of producing either lateral dislocation; the displacement taking place, obviously, in the *opposite* direction to such force. *Indirect* violence; as a fall from a height upon the bottom of the foot may have a similar effect; if the foot have a sufficient inclination to either side, to thus direct the force of the impulse in favour of dislocation to *that* side. forcible flexion or extension, may produce dislocation backwards or forwards, respectively. A fall on the bottom of the foot, the body inclining backwards or forwards, tends also to produce dislocation in the *opposite* direction. But a person jumping out of a carriage in rapid motion and alighting on his feet, is liable to dislocation *in* the direction of the momentum. Thus, from jumping out forwards, the dislocation will be forwards; from jumping out backwards, the dislocation will, probably, be backwards.

**TREATMENT.**—All these dislocations are reduced in like manner. The leg should be flexed to a right angle on the thigh, to relax the conjoined gastrocnemius and soleus muscles; extension is then made from the foot in a line with the long axis of the leg, taking care that the foot inclines midway between flexion and extension of the ankle-joint, and by drawing

with one hand on the back of the foot and the other hand on the heel. Pressure on the end of the tibia, according to the direction of the displacement, will further aid reduction. Lateral splints with foot-pieces may then be applied; but I prefer a McIntyre's trough splint, as affording a more equable support to the whole leg. The swelling around the joint is often considerable; it, however, subsides under the influence of rest and the usual topical applications.

*Compound* Dislocations of the Ankle-joint, are probably the most common of all compound Dislocations. Among the cases recorded by Sir

A. Cooper, 45 were dislocations of this joint; and among Hamilton's cases, 4 were dislocations inwards, and 1 a partial dislocation forwards. The displacements are the same, and arise from the same causes, as in simple dislocation of the ankle; but compound dislocation derives its importance from the size of this joint, and the violence of the injury. (Fig. 214.)

FIG. 214.

*Treatment.*—Preservation of the foot—without any operative interference—proves successful in a far larger proportion of cases than in similar injury of the knee-joint. The wound should be closed and the leg kept at rest on a McIntyre's splint. Protrusion of the tibia with comminution, as often happens in backward dislocation, allows of *excision*, in most cases. But severe contusion or laceration of the soft parts, including injury to the tibial arteries—in addition to compound dislocation of the joint—imperatively demands *primary amputation*. The usual consequences of inflammation, suppuration and sloughing, or gangrene, may render *secondary* amputation necessary, when an attempt to save the foot has failed.

**DISLOCATIONS OF THE ASTRAGALUS.**—This bone is sometimes displaced from under the tibia, and thrown—(1) *forwards*, (2) *outwards*, or (3) *inwards*; the two latter displacements probably being *inclinations* of the bone forwards in either of these directions, thus constituting two lateral dislocations; and occasionally it may be displaced (4) *backwards*. It may also—observes Hamilton—be simply *rotated* on its lateral axis, without much, if any, lateral displacement; and lastly, it is, sometimes, driven *upwards* between the tibia and fibula, tearing away the intermediate ligaments and generally fracturing one or both these bones.

(1. 2. 3) Dislocation *forwards*, and *outwards*, or *inwards*; may be complete or incomplete. *Complete* dislocation of the astragalus represents its detachment from the os calcis and scaphoid bones, and its displacement from under the malleolar arch forwards; the bone lying upon the scaphoid and cuneiform bones. *Incomplete* dislocation signifies the separation of this bone from the scaphoid only, and the ejection of its head on to the external cuneiform or cuboid bones; the body of the astragalus still retaining its connexion with the os calcis, and malleolar arch.

(4) Dislocation *backwards* is a dislodgment of the astragalus on to the os calcis behind the tibia, in the interval between it and the tendo-Achillis.

**SIGNS.**—The projection of the astragalus which can be felt and seen, in each of these directions of dislocation, is alone sufficient to indicate the nature of the injury. (Fig. 215.) The malleoli are nearer the sole of the foot, the tibia having fallen down upon the os calcis; and there may be some flexion or extension of the foot.

FIG. 215.

The *Causes* of astragaloid dislocation resemble those of ankle-joint dislocation. Thus, a fall from a height upon the bottom of the foot, accompanied with violent abduction, adduction, flexion or extension, may determine a dislocation of the astragalus—forwards, inwards, outwards, or backwards; a wrench or twist of the foot, in machinery or in the wheel of a carriage, for example, is another mode of production. A direct blow may also be the cause.

*Unreduced* dislocation of the astragalus is a not uncommon result, reduction being often very difficult and having proved impossible. Recovery of the use of the foot has been attained so far as to enable the person to walk again, but with considerable crippling.

Reduction, on the other hand, even when promptly and easily effected, has been followed by inflammation and gangrene, resulting in death.

**TREATMENT.**—Reduction—when practicable—can be accomplished in the same manner as in dislocations of the ankle. Flexion of the leg to a right angle with the thigh, relaxes the muscles of the calf; and then extension from the foot, with counter-extension from the lower part of the thigh, aided by pressure on the displaced bone, will perhaps replace it. Division of the tendo-Achillis is said to have facilitated reduction in obstinate cases.

The probability of effecting reduction depends very much on the dislocation being *incomplete*; *complete* dislodgment of the bone will be very difficult to overcome. The tibia and os calcis, powerfully drawn together, can hardly be separated to an extent sufficient for the return of the bulky astragalus; itself also bound down by the extensor tendons, in forward dislocation, and by the tendo-Achillis in backward dislocation.

Should reduction have proved impossible, the integument over the projecting astragalus, will probably slough and expose the bone; anticipating this result it is better forthwith to proceed to *excision*, even if the dislocation be *simple*.

*Compound* Dislocation presents no peculiarity otherwise than the more serious nature of the injury, from exposure of the bone, and as occasioned by more severe violence. (Fig. 216.)

Excision, or amputation, are the only alternatives.

**DISLOCATIONS OF THE OTHER TARSAL BONES.**—Such dislocations are very rare. The *Calcaneum* may, however, be dislocated *outwards* from the astragalus alone; or from the cuboid bone simultaneously, in a direction *outwards* and *upwards*. It has also been found dislocated outwards from the astragalus and inwards upon the cuboid bone.

The *deformity* is sufficiently characteristic. These dislocations have arisen from a fall on the heel.

FIG. 216.

The *Scaphoid* and *Cuboid* bones, together, may be dislocated from the astragalus and calcaneum, *upwards* — the middle tarsal dislocation of Malgaigne. The foot is shortened, and the instep raised; presenting the deformity of club-foot. This injury also has arisen from a fall, but on the ball of the foot.

The *cuboid* bone *alone* may, it is said, be dislocated upwards, inwards, and downwards; but Malgaigne has found no case recorded of this dislocation alone, unaccompanied with that of one or more of the other tarsal bones.

The *scaphoid* bone *alone* has been found dislocated from the cuneiform bones, its connexion with the astragalus remaining undisturbed. The dislocation was compound, yet—after reduction—the wound healed rapidly, and recovery soon became established.

Dislocation of the scaphoid from both the astragalus and cuneiform bones, has occurred in several instances.

The *Cuneiform* bones may be partially dislocated, and without having separated from each other; of which two or three examples are recorded. The *internal* cuneiform bone alone, has been dislocated inwards. Sir A. Cooper saw two instances, in both of which the same appearances were presented; great projection of the bone inwards, with some elevation by the action of the tibialis anticus muscle, and the bone no longer remained in a line with the metatarsal bone of the great toe. A fall from a height produced this dislocation in the one case; and in the other, a fall from a horse, the foot being caught between the horse and the curb-stone. In neither case was the bone reduced; but the subject of the first of these accidents walked with only a little halting.

The *Treatment* of all these dislocations of the Tarsal Bones is the same. Reduction may, possibly, be effected by pressure on the displaced bone. A compress and foot-splint, will then be required to allow the bone to regain its ligamentous connexions.

DISLOCATION OF THE METATARSAL BONES—is, also, very rare. The metatarsal bone of the *great toe* has been dislocated upwards, an instance of which from direct violence was seen by Liston, and reduced. The *inner three* metatarsal bones were dislocated downwards and backwards, in a case recorded by Tufnell, and as resulting from a fall upon the leg

by a horse rolling on its rider; Erichsen also found the *outer* three metatarsal bones dislocated downwards, by the pressure of a "turn-table" on a railway.

The *causes* are usually a fall backwards or forwards, the anterior extremity of the foot being wedged under some resisting body. Various crushing accidents also sometimes occasion these dislocations.

The *treatment* must be conducted on ordinary principles.

Dislocations of the PHALANGEAL BONES of the toes, resemble those of the Fingers, and do not require a separate notice. In a case—related by Sir A. Cooper—all the smaller toes were dislocated forwards; a projection existed at their roots, and the extremity of the metatarsal bones bulged under the first phalanx of the corresponding toes. This displacement had been caused by a fall, from a considerable height, upon the extremities of the toes. Several months had elapsed, and reduction could not be effected. Walking was rendered more tolerable by wearing a piece of hollow cork at the bottom of the inner part of the shoe, to prevent the pressure of the metatarsal bones upon the nerves and blood-vessels.

CONGENITAL DISLOCATIONS OF THE BONES OF THE FOOT.—These Injuries are associated with the various forms of Talipes or Club-foot.

## CHAPTER XXXIV.

### DISEASES OF JOINTS.

UNLIKE Diseases of Bone—wherein the osseous texture or bone proper, the periosteum, and the medullary membrane or endosteum, are *less separately* and distinctly the seat of any particular morbid condition; Diseases of joints relate to the synovial membrane, the articular ends of bone, and the articular cartilages, not to mention the ligaments, as, *severally*, the *seats* of disease; although any such morbid condition, isolated primarily, often spreads to the adjoining structures, secondarily. Thus, the component structures of the joints have each an individuality in relation to Disease; and Diseases of the joints have reference essentially to these component structures.

This pathologically analytical view of joint-diseases—with regard to their seat and origin in joint-structures, is due to Sir B. Brodie; prior to whose observations, both clinical and pathological, Diseases of the joints were confounded under the ambiguous terms, "Arthritis," and "White Swelling."

SYNOVITIS.—INFLAMMATION OF THE SYNOVIAL MEMBRANE.—*Structural Condition.*—An inflamed synovial membrane is more vascular than natural, in the form of crimson spots or diffused redness, and loses its glistening appearance. The synovial secretion is increased in quantity, and thinner. These are the earliest changes. As inflammation proceeds, the membrane acquires a pulpy thickening and opacity, by interstitial exudation, and lymph is effused from its inner surface, giving it a granular or villous appearance, and forming flakes in the synovial fluid, which also accumulates in quantity. Some effusion may even occur in the subserous cellular tissue. This represents the *adhesive* stage of synovitis; an event, however, which rarely supervenes, as the opposed surfaces of the

interior of the synovial Capsule become yet more separated by its increasing distension. Subsequently, pus may be secreted within the capsule, which thus becomes converted into an *abscess*.

*Signs.*—The knee-joint may be taken for example, in regard to Synovitis, as it is more commonly affected than any other joint. Coincident with the earliest stage of inflammation, *pain* is experienced by the patient, and usually referred to a particular spot, perhaps the inner edge of the patella; afterwards extending over the whole articulation. The pain has no specially distinctive character. It is severe in proportion to the depth of the articulation and the unyielding nature of the ligamentous and other surrounding structures. It is also most intense in synovitis of a rheumatic or gouty origin, and as if the joint were compressed by a vice, or being violently torn open. In a period varying from two or three hours to as many days, according to the intensity of the inflammation, *swelling* makes its appearance. The consistence and shape of this synovial swelling are characteristic. At first, fluid and fluctuating, it becomes semi-solid as lymph is effused, and again resumes its original fluidity in the event of suppuration. But the shape of this swelling is even more remarkable. Throughout the course of synovitis, it corresponds to the shape of the synovial capsule; presenting that outline more clearly according to the degree of distension, and as modified by the compression of surrounding ligaments and tendons. The swelling, therefore, varies in form with each articulation, and its relation to the ligaments and tendons. Thus, in the knee, the swelling of synovitis is most conspicuous as a protrusion on either side of the ligamentum patellæ, betwixt it and the lateral ligaments, and rising up above the patella, bulges in a uniform shape as high as the distended capsule may extend. In the elbow, the swelling projects on the posterior aspect of the joint, above the olecranon, and under the extensor muscles of the forearm. In the ankle, it presents on each side, between the lateral ligaments and the anterior tendons. In other joints less superficial, as the shoulder and hip, the swelling of synovitis is less perceptible; in the one being obscured by the cushion of the deltoid muscle; in the other, however, an evident fulness of the groin and sometimes of the nates, can be detected. The wrist-joint is far less frequently subject to synovitis; but here a general fulness and some bulging between the tendons—extensors and flexors, shows a conformity to the rule of characteristic swelling. Heat, and, possibly, redness of the skin around the joint, will also be more or less evident; but these signs are not diagnostic. The attitude of the limb is more or less peculiar, or becomes so. The joint is placed in the position most easy to the patient, and usually becomes semi-flexed. Constitutional febrile disturbance, in some degree, accompanies these local symptoms.

*Causes.*—Exposure to cold, or some occasion of injury, as a blow or fall, may give rise to synovitis. The disease thus occurs in joints which are most superficial and exposed, as the knee and ankle. But these causes are usually backed by some predisposing constitutional condition; especially rheumatism, scrofula, constitutional syphilis, or formerly, by the poisonous administration of mercury. Several joints may then be affected simultaneously. Inflammation of the synovial membranes also ensues, occasionally, from gonorrhœa or purulent ophthalmia. Such synovitis has been incorrectly named “gonorrhœal rheumatism,” although not apparently depending on a rheumatic condition. Gonorrhœal synovitis would be a more correct designation. Arising after gonorrhœa of a few weeks’ duration,

it affects one or more joints. The gonorrhœal discharge may subside, or continue concurrently. Serum rather than lymph is effused into the joint, and the disease terminates without disorganization, in a few weeks. Or, it proceeds, sometimes, to ulceration of the cartilages, and continues for months or a year or two. In one such case, under my care, the knee-joint became firmly ankylosed.

Pyæmia induces a low inflammation of the joints, the special character of which is its abundant sero-purulent effusion, and consequent swelling; unattended by pain, heat and redness, the ordinary symptoms of inflammation. Ulceration of the cartilages ensues if the patient lives long enough.

*Terminations.*—(1) *Resolution* commonly occurs; the pain, swelling, and other symptoms subsiding, and the joint regaining apparently a healthy condition. (2) *Adhesion*, or complete fibrous ankylosis, sometimes results; the fluid portion of the effusion being absorbed, the surfaces of the synovial membrane come together and are partially united by fibrous adhesions; thus leaving the joint much stiffened, in the state of *fibrous ankylosis*. (3) *Fluid* remaining in the synovial capsule; the swelling becomes persistent, with laxity and weakness of the joint; constituting *chronic synovitis*. An extreme degree of this condition has been named *hydrarthrosis* or *hydrops articuli*,—dropsy of the joint. (4) *Suppuration* and *abscess* having occurred; the articular cartilages undergo ulcerative disintegration, and the subjacent bone is liable to become carious—thus ending in total disorganization of the joint; or ankylosis supervenes—sometimes fibrous and stiffly moveable, sometimes bony and fixed. The head of the femur and acetabulum, for example, both denuded of cartilage, may be found to have undergone ankylosis—fibrous, or even osseous. Or, an articular abscess opens, attended with a temporary relief of the symptoms; but a wasting discharge ensues, and the inflammatory fever is exchanged for hectic, under which the patient would ultimately sink from exhaustion, unless the disorganized joint has been removed in time.

*Treatment.*—Absolute *rest* of the joint should be observed, as primarily important; the limb being placed in that *position* which is most easy to the patient, and most convenient in the event of any stiffness remaining. A somewhat flexed position will, generally, best answer this twofold purpose. The limb may be sufficiently steadied by laying it on a soft pillow, which thus partially envelopes the joint; or, a suitable splint should be applied to insure rest. Local depletion by leeches followed by warm fomentations, or cold lotions or irrigation will be appropriate, according to the intensity of the inflammation. *Constitutional* treatment has reference to the inflammatory fever, and any constitutional cause of the inflammation. Hence, saline antimonials with perhaps calomel and opium, may be sufficient to subdue the febrile disturbance and check effusion; or the special treatment for rheumatism, constitutional syphilis, or other such causative condition, may be requisite.

Gonorrhœal synovitis is amenable to the same treatment as that arising from rheumatism. Thus, colchicum and iodide of potassium sometimes prove remedial. But the disease, in most cases, runs its course; or a change of climate from a cold and damp atmosphere to the southern coast, may be followed by a speedy subsidence of the symptoms.

By this plan of treatment, synovitis, in an early stage, will probably terminate by resolution or slight effusion.

*Chronic synovitis* must be treated with a view to the removal of the accumulated effusion, and consequent weakness of the joint. Counter-irritation in the form of blisters should be employed to overcome any persistent inflammation; followed by stimulating embrocations, and pressure to promote absorption. Two or three blisters in succession are certainly preferable to a single blister kept open with savine ointment. The discharge produced by savine ointment soon ceases, and the surface of the skin acquires a mammillated appearance from enlargement of its papillæ. The blisters should not be applied directly over the inflamed joint, but in the neighbourhood. Thus, in the case of the knee, a blister applied on either side of the thigh just above the joint; and with regard to the hip, a blister may be placed on the groin or nates. Of stimulating embrocations, a liniment of turpentine and olive oil, or the iodine paint, are perhaps most efficacious. Pressure can be applied by means of a gutta-percha or pasteboard splint, moulded to the joint; or the joint may be strapped with soap-plaster spread upon leather. The *emplastrum ammoniaci cum hydrargyro* conveniently combines both stimulation and pressure. Injection of the joint with tincture of iodine has been much employed by Velpeau, Jobert, and Bonnet; and it is recommended with more reservation by Erichsen. The tincture is diluted with two or three parts of water. A small trocar is introduced into the joint, a portion of the serous fluid let out, and a corresponding quantity of the iodine solution thrown in, and after being left for a few minutes, is allowed to escape. Inflammation thus produced has, it is said, in no case been followed by serious consequences, but frequently by a complete cure without ankylosis. In a case of hydrarthrosis of the knee, in an old man; Mr. Erichsen drew off about six ounces of thin synovia, and injected a drachm of strong tincture of iodine into the joint. Only slight inflammation ensued, and the disease, of two years' duration, was completely cured. The precautions necessary are; a very chronic, passive, state of effusion, and that no air should enter the joint. Constitutional treatment, by the influence of iodide of potassium and cinchona bark, cascarilla, or other tonics, will aid these local measures.

*Suppuration* and abscess, in the interior of a joint, should be met promptly, by evacuation of the matter. The presence of pus having been first assuredly ascertained by puncturing the joint with a grooved needle; an opening with a bistoury should be made forthwith, freely, and in a dependent situation. This proceeding was, I believe, originally advocated by Mr. Gay, and it has been sanctioned by subsequent experience. Perfect rest of the joint must then be secured by splints, and the limb placed in the position most convenient for use, in the event of ankylosis. A suitable kind of ankylosis having been attained, fibrous or osseous, according to the use of the limb; it will be unnecessary to have recourse to further operative interference, by excision or amputation. Constitutional treatment consists in the tonic medicinal resources and supporting regimen, requisite to sustain the exhaustion of hectic.

CHRONIC RHEUMATIC SYNOVITIS, OR CHRONIC RHEUMATIC ARTHRITIS.—*Structural condition.*—This inflammatory disease involves other joint-textures besides the synovial membrane; but that is the texture first affected. Sir B. Brodie, Cruveilhier, and Dr. R. Adams, alike concur in this view of the structural origin of the above named disease. Hence, the substantive term *synovitis* seems preferable to that of *arthritis*, proposed by Dr. Adams; the etymological signification of the latter term including

inflammation of any or all the structures of a joint (*ἄρθρον*, a joint). That would appear also to be a revival of the old nomenclature, which Sir B. Brodie's pathological investigation, with reference to the *earliest* changes in the various "Diseases of the Joints," was specially designed to correct, and has so advantageously superseded.

Chronic Rheumatic Synovitis differs only from ordinary Chronic Synovitis in certain particulars as to its pathology, and treatment, which are, however, worthy of separate notice. The inflammation of the *synovial membrane* seems to affect the vascular fringe-like processes of this membrane more particularly, which are much developed and injected; the internal surface of the capsule presenting the appearance of a villous mucous membrane. Effusion of fluid within the joint, takes place to a moderate amount, and is eventually absorbed. But the membrane itself remains thickened and fibrous; while osseous deposits frequently form, partly in its substance, principally around the joint, connected with the periosteum and articular ends of the bones. Hence the term *nodosity* of the joints, proposed by Dr. Haygarth, as expressing one of the most distinctive features of chronic rheumatic synovitis or arthritis. The *ligaments* become relaxed; the *articular cartilages* undergo peculiar changes; becoming fibrous and having a yellowish hue, ultimately being destroyed, and presenting patches of ivory-like bony material or porcellanous deposit, white, smooth, and glistening. This acquires even a high polish under the attrition of the surfaces, and linear furrows are formed in the directions of friction by the movements of the joint. Inter-articular ligaments and fibro-cartilages are more or less destroyed and disappear; thus the round ligament in the hip-joint, and the long head of the biceps in the shoulder-joint, are removed by absorption. The sub-cartilaginous *osseous* structure is much condensed, and the whole articular end of the bone enlarged and deformed by the surrounding osseous growths; while the *articular surfaces* become singularly altered in *shape*. Thus, the globular heads of the femur and humerus are flattened and expanded, and their necks shortened; the corresponding articular cavities also being enlarged and shallow. These alterations with the bony buttresses thrown out around the articular ends, have sometimes been mistaken for fracture with bony union, in examining such pathological specimens of the neck of the femur or humerus.

The *Signs* of chronic rheumatic synovitis or arthritis are distinctive;—pain, enlargement and ultimate deformity of the joint, rigidity or stiffness, and a peculiar crackling noise on moving the joint. The pain is not acute, but of an aching character, worse at night, increased by motion, and aggravated by cold and moisture; it is, in short, rheumatic pain. The general health may remain comparatively unaffected.

The *Causes* of this disease always have reference to the constitutional condition of Rheumatism, and sometimes, exposure to cold or injury as an exciting cause. Thus chronic rheumatic synovitis may result from rheumatic fever or from repeated attacks of rheumatism; or in a person predisposed, direct exposure of a joint to cold or some slight injury, as a sprain, may evoke the disease. Many joints are liable to be affected, the disease passing from joint to joint without relieving those originally attacked; or only one joint may be affected. The larger joints, especially the hip, seem to be most frequently attacked in males; the smaller joints, as those of the fingers, in females. But, apart from this relative difference, both sexes would seem to be nearly equally liable to the disease. Age

has no special proclivity; the disease usually occurs after mid-life, but it may also appear in young persons. No social condition is exempt; the poorly fed and hard-worked being prone, the luxurious and indolent, subject to this disease; in the latter class, assuming the character of *rheumatic gout*.

*Course and Terminations.*—Chronic rheumatic synovitis is singularly persistent, evincing little tendency to subsidence, or termination by resolution. The irregular enlargement and deformity of the joints, with the weakened state of the ligamentous structures, and altered shape of the articular surfaces, predispose to partial dislocations; leaving the patient stiffened and crippled in his movements, and ultimately reduce him to a helpless condition. Loose cartilages, moreover, are apt to form in the joints. Suppuration rarely, if ever, occurs; the disease—apart from any temporary effusion of fluid—is essentially a *dry* disease of the joints. Ankylosis also is a rare event; although the increasing articular rigidity, and wasting of the diseased muscles, have an equivalent result.

*Treatment.*—*Preventive* measures, in the early stage of this disease, may succeed in averting its destructive consequences; but any curative measures, for the removal of the osseous deposits or out-growths, and restoration of the disorganized state of the joints—in respect to ligaments, synovial membrane and cartilages, will have scarcely any avail. *Local* treatment—in the early stage—is that of synovitis. Rest of the joint, and slight topical depletion by a few leeches, may now prove efficacious. But, as the symptoms of inflammation subside, leaving some structural results—in thickening of the synovial membrane and effusion within the joint—counter-irritation, by means of blisters, or iodine paint, will become advantageous. Stimulant embrocations and friction, as by shampooing or local douches, and motion, may then succeed in recovering the use of the joints. The *constitutional* treatment should be that of rheumatism. In the early stage, bicarbonate of potash, in large doses, with wine of colchicum, may arrest the progress of the disease. Subsequently, iodide of potassium and guaiacum seem to have more controlling influence. Free action of the skin must be promoted by sudorific medicines, as Dover's powder and hot air-baths; while a rigorous attention to diet will be indispensable when the disease has a *gouty* character, with dyspeptic symptoms, denoting a constitutional origin of that kind. Mineral waters, coupled with a due observance of dietetic precautions, sometimes prove singularly beneficial in rendering joints supple and restoring the general health, at least for a time. The waters of Bath or Buxton in this country, Vichy, Wiesbaden, Carlsbad, Ems or Aix-la-Chapelle on the Continent, are thus hopeful resorts for the victims of chronic rheumatic synovitis.

SCROFULOUS SYNOVITIS.—*Structural Condition.*—A pulpy or gelatinous degeneration of the synovial membrane, resulting from inflammation of a chronic character, modified by a scrofulous constitutional condition.

The synovial membrane, in this state, is thickened, and converted into a soft yellowish or light brown gelatinous material; more vascular also than the healthy membrane. This change may be partial in its extent, affecting only the membrane reflected over the ligaments, or over the cartilages. Sir B. Brodie, who first described this disease, relates such cases as shown by dissection. The articular cavity becomes diminished as the thickening upon the *inner* surface of the membrane encroaches on the joint; and, this extension proceeding most freely in the loose synovial folds which surround the cartilages, they are often concealed by the new

formation. A similar pulpy material forms in the areolar texture around the outer surface of the membrane, which thus becomes infiltrated and condensed. This gelatinous material—according to Mr. Barwell—results from a failure in the process of development of the products of inflammation; in acute and healthy synovitis, a fibrous or areolar tissue being produced; whereas in scrofulous inflammation, development does not advance beyond the first form of crude cell-structure. Many intermediate gradations, however, may be found between these two conditions.

The knee-joint is most commonly affected.

*Signs, and Diagnosis.*—In an early stage, a sense of stiffness of the joint is experienced and tumefaction appears, beginning almost imperceptibly, but slowly and gradually increasing; with absence of pain, even on moving the joint. These early symptoms are not very characteristic. In a more advanced stage, a very considerable enlargement is presented, generally of an irregular shape, colourless and elastic, without any distinct fluctuation. This disease most resembles scrofulous caries of the articular ends of the bone in the joint affected. But the *swelling* is diagnostic, in its being more obviously referable to the synovial membrane than to the end of either bone. From cancerous disease of either articular end of bone, the same feature of distinction may be available for diagnosis; while the whiteness of the skin contrasts with the reddish or purplish discoloration which sooner or later supervenes in malignant disease, as the skin becomes involved. The lymphatic glands also are not contaminated.

*Course and Terminations.*—As the disease progresses, the cartilages undergo *ulceration* in spots; though these spots are not, necessarily, at first, in direct relation with the pulpy synovial membrane. The changes which ensue are fully described in tracing the Ulceration of Articular Cartilages. Abscess forms within the joint, or in the substance of the swollen membrane; and making its way to the surface, opens by various sinuous apertures. Hectic supervenes.

Occasionally, the disease subsides by apparently a retrograde course of restoration. The gelatinous growth is directed inwards towards the articular cavity, which it tends to fill up; while the material itself becoming more fibrous, and contracting, still further diminishes the cavity. *Anchylosis* of the osseous surfaces completes this process of recovery. Rarely, the synovial membrane itself is restored to a healthy state; *absorption* taking place, and the articulation remaining structurally sound.

*Treatment.*—Remedial measures must have regard to the constitutional condition, and hence the treatment of Scrofula is here appropriate. Local treatment consists, in absolute rest of the joint, and the observance of a suitable position in the event of ankylosis. Counter-irritation should be applied, cautiously. The actual cautery is, however, strongly recommended by Mr. Barwell, when enlargement is proceeding without any notable inflammation. The iron should be white hot, and applied in lines, about an eighth of an inch broad and three inches long, parallel to the axis of the limb. Four such lines are recommended for the knee, two on each side of the patella, at least an inch apart; dry lint being then applied. This proceeding resembles the “firing” of a joint, as practised in veterinary surgery. The advantage of counter-irritation, by means of the actual cautery and thus applied, is said to be not only its derivative effect, but the pressure which ensues from the contracting

cicatrices. Scott's dressing may be used as a means of counter-irritation, and the plaster affords more support, when the swelling is reduced to a passive state. Friction and gradual motion will then finish off the disease, and restore the use of the joint.

Ulceration of the articular cartilages, with abscess, and destruction of the joint, necessitate the removal of the diseased part, either by excision or amputation. The latter operation may be sometimes imperative, owing to the constitutional exhaustion rather than the extent of the disease. Loss of limb will then be alternative to the loss of life; the patient, otherwise, inevitably sinking under prolonged hectic.

SCROFULOUS DISEASE OF THE JOINTS, or scrofulous inflammation and *caries* of the cancellated structure of the articular ends of Bone.—*Structural condition.*—The alterations of the cancellous structure in this state of disease, are fully described in DISEASES OF BONE. The changes alluded to may be summed up as inflammation and consequent caries; differing only from ordinary inflammation of bone in the nature of the products associated with the disintegrative transformation. At first, the cancellous structure is simply more vascular than natural, then it becomes softened, and porous; while the cancelli are filled with a reddish gelatinous fluid, and ultimately an opaque, friable, tuberculous matter. Caries appears frequently in separate points of the cancellous tissue, which gradually extending, coalesce.

This disease is commonly situated in the articular ends of the long bones; particularly, the head of the femur, in scrofulous disease of the hip-joint; in the head of the tibia or lower articular end of the femur, in similar disease of the knee-joint; in the bones of the tarsus; in those of the carpus; in connexion with the elbow or shoulder joints, occasionally; and not unfrequently in the cancellous tissue of the bodies of the dorsal or lumbar vertebrae. Nor do these situations exhaust the list of bones liable to be affected by scrofulous caries.
